The cellular utilization of oxygen in the tissues is blocked by cyanide, hydrogen sulfide, and azide because of their affinity for cytochrome oxidase. Cyanide exerts its toxic effects by interrupting electron transport in the mitochondrial cytochrome electron-transport chain. In addition, interferences with the enzyme systems producing ATP is a well-defined mechanism of toxicity. The ultimate formation of ATP in the cell by the oxidation of carbohydrates may also be blocked at other sites. For example, rotenone and antimycin A interfere with specific enzymes in the electron-transport chain, nitrophenols uncouple oxidative phosphorylation, and sodium fluoroacetate inhibits the citric acid (Krebs) cycle. Nitrophenols interfere with the production of high-energy phosphates in mitochondria. They prevent the phosphorylation of adenosine diphosphate (ADP) to ATP, but electron flow and oxygen consumption continue. In addition to inducing loss of cell function due to depletion of ATP, this type of uncoupler also causes a marked elevation of body temperature due to excess heat production. Toxicity resulting from blockage of the tricarboxylic acid cycle occurs in organs heavily relying on the availability of a continuous energy supply and results in cardiac and nervous system toxicity. A classic example for a mechanism inhibiting the Krebs cycle is termed “lethal synthesis” and is exemplified by fluoroacetate, which is incorporated into the Krebs cycle as fluoroacetyl coenzyme A, inhibits the aconitase-catalyzed conversion of citrate to isocitrate, and interrupts the Krebs-cycle (Fig. 49). The Krebs cycle is the major degradative pathway for the generation of ATP and also provides intermediates for biosynthesis. For example, the majority of the carbon atoms in porphyrins comes from succinyl CoA and many of the amino acids are derived from α-ketoglutarate and oxalacetate. Hence, interruption of the Krebs cycle by the incorporation of fluoroacetate may be lethal for the cell.

Figure 49. Lethal synthesis

Incorporation of fluoroacetate in the Krebs cycle; formation of fluorocitrate and inhibition of aconitase results in blocking of the tricarboxylic acid cycle and interruption of cellular energy production

The consequences of ATP depletion include impairment of membrane integrity, ion pumps, and protein synthesis. Depending on its extent, energy depletion will inevitably lead to loss of cell function and cell death.

3.3. Binding of Xenobiotics to Biomolecules

Many toxic chemicals exert their effects by covalent linkage of reactive metabolites to essential macromolecules of the cell. Xenobiotics may become covalently bound to the active site of enzymes or to other macromolecules whose function is critical to the cell. These include proteins (Section Binding of Xenobiotics or their Metabolites to Cellular Proteins) and lipids (e.g., as membrane structural elements; see Section Interaction of Xenobiotics or their Metabolites with Lipid Constituents) and nucleic acids (see Section Interactions of Xenobiotics or their Metabolites with nucleic Acids). The linkage generally involves binding of electrophilic metabolites to nucleophilic sites such as thiol, amino, and hydroxyl groups in the side chains of proteins and is essentially irreversible; it depends only on the turnover of the macromolecule in question for the repair of the lesion. In addition, other toxins may bind to proteins and impair their normal function without first being converted to reactive intermediates.

3.3.1. *Binding of Xenobiotics or their Metabolites to Cellular Proteins*

Many toxic substances exert their effects via binding to the active sites of enzymes or other proteins that are critical to cellular function. For example, hydrogen cyanide binds with high affinity to the Fe^{3+} ion in cytochrome oxidase and thus blocks the last step in the mitochondrial electron-transport chain, which is important for cellular energy production. This single and highly specific site of action is responsible for the rapid induction of the often fatal toxic effects of cyanide. Carbon monoxide binds to the reduced form of iron in hemoglobin, whose physiological function is to bind, transfer, and deliver oxygen to tissues. Since carbon monoxide has a 210-fold higher affinity to this binding site than oxygen, very low concentrations of carbon monoxide in the atmosphere are sufficient to displace the physiological ligand and produce severe toxic effects. Thus, 0.1% carbon monoxide in the atmosphere can occupy roughly 50% of the available hemoglobin binding sites, because on the basis of the 210-fold higher affinity to hemoglobin compared with oxygen, 0.1% carbon monoxide is equivalent to 20% oxygen in the atmosphere.

Another example for the importance of protein binding in toxicity is the binding of metal ions to protein thiol groups. Many toxic metals such as lead, mercury, cadmium, and arsenic bind to proteins with free sulfhydryl groups, which contributes by as-yet largely unknown mechanisms to the toxicity of these metals. Induction of porphyria by lead, mercury, and other metals is based in part on the inhibition of specific enzymes of heme biosynthesis and results in the accumulation of specific intermediates in heme synthesis. The binding of cadmium to the sulfhydryl-rich protein metalothionein results in active concentration of the metal-metalothionein complex in the proximal tubules of the kidney. Catabolism of the metal complex in the lysosomes of proximal tubule cells with concomitant liberation of the toxic metal results in nephrotoxicity, a common effect of cadmium exposure in humans and experimental animals [137].

Binding to active sites in enzymes may result in the inhibition of biochemical pathways vital to the cell. The induction of toxic effects may be due to accumulation of a specific enzyme substrate or insufficient amount of substrate available for normal physiological function. For example, many organophosphate pesticides inhibit cholinesterases by covalently binding to the active site, the amino acid serine of cholinesterase. Since the phosphorylated cholinesterase is stable, the covalent binding results in inhibition of enzymatic activity (Fig. 50). Due to the impaired cleavage, acetylcholine accumulates at cholinergic synapses and neuromuscular junctions. Organophosphates thus produce the typical signs of acetylcholine poisoning, such as increased salivation and lacrimation, abdominal cramps and diarrhea, cough, bronchoconstriction and breathing impairment, mental confusion, headaches, tremor, and coma.

Figure 50. Mechanisms of cholinesterase inhibition by organophosphate pesticides

Compare the $t_{1/2}$ of the enzyme complex with the physiological substrate acetylcholine (a few milliseconds) to the $t_{1/2}$ of the enzyme complex with organophosphate pesticides (several days).

Protein modifications may also be the basis for immunosuppressive effects and chemical-induced allergy. For many chemicals causing necrosis, binding to cellular macromolecules is essential for the expression of toxic effects. However, in most cases the temporal sequence of events that is triggered by covalent binding and the cause–effect relationships between these events are not fully understood.

3.3.2. *Interaction of Xenobiotics or their Metabolites with Lipid Constituents*

Lipid peroxidation in biological membranes by free radicals initiates a series of events finally causing cellular dysfunction and cell death. The formation of radicals during peroxidation is a self-propagating process; the reaction may be started by organic radicals formed during biotransformation or by oxygen radicals formed by disruption of cellular energy metabolism. The initiation of lipid peroxidation by interaction of free radicals with polyunsaturated fatty acids to form lipid peroxy radicals, which then produce lipid hydroperoxides and other lipid peroxy radicals, has been proposed as a critical step leading to cell injury and death. Peroxidative damage to plasma membrane lipids may cause impairment of membrane integrity and, finally, rupture of the plasma membrane. In addition, breakdown of the membranes of subcellular organelles such as those of the mitochondria, the endoplasmic reticulum, and lysosomes may also contribute to induction of cell death. The end products of the breakdown of membranes, mainly unsaturated aldehydes, may also produce toxicity in distal tissues. Induction of lipid peroxidation is involved in the toxicity of many chemicals which are converted to free radicals. A well-studied example is carbon tetrachloride, which is converted by cytochrome P450 to the trichloromethyl radical (CCl_3) and the trichloromethylperoxyradical (CCl_3O_2). Radicals and reactive oxygen species may interact with the major soluble cellular thiols, glutathione (GSH), and thiol-containing proteins. Depletion of cellular glutathione and modification of thiol-containing proteins by oxidation or mixed disulfide formation with glutathione and other low molecular mass thiols may results in oxidative stress in the cell.

An important function of reduced glutathione is to protect the sulfhydryl groups of proteins by keeping them in the reduced state. Depletion of intracellular glutathione stores appears to be a prerequisite for the onset of significant oxidative stress. Many critical enzymes in the cell depend on reduced thiol groups (SH groups) to maintain their activity; hence, concentrations of reactive oxygen species in excess of that necessary to deplete intracellular glutathione can induce oxidation of protein thiols to form disulfide linkages, thereby impairing enzymatic activity. Although the direct covalent interaction of electrophilic chemicals with protein thiols may contribute to enzyme inhibition; it appears that reversible oxidation of the thiol group as a result of oxidative stress plays a more important role. One group of thiol-containing enzymes whose impairment as a result of oxidative inactivation may play a critical role in cell injury and death are the Ca^{2+}-transporting membrane systems.

3.3.3. *Interactions of Xenobiotics or their Metabolites with nucleic Acids*

Electrophilic compounds, usually formed by oxidative biotransformation of xenobiotics, may also interact with various nucleophilic sites in DNA, principally O-6, N-7, N-2, and C-2 of guanine. Moreover, other types of DNA damage may occur as a consequence of covalent binding of electrophiles or by interaction of DNA with reactive oxygen metabolites (Table 21).

Table 21. Types of DNA damage induced by xenobiotics

Type of DNA-damage	Examples
Modifications of purines and pyrimidines	alkylation by electrophiles, oxidation to 8-hydroxyguanosine and other oxidized purines, UV-induced formation of thymidine dimers
DNA strand breaks	oxygen radicals, activation of calcium-dependent endonucleases
AP lesions (apurinic, apyrimidinic sites)	loss of DNA bases through labilization after covalent binding of xenobiotics to specific sites in purine and pyrimidines
DNA cross-links	bifunctional electrophiles react with nucleophilic sites in both DNA strands (interstrand cross-link) or with two bases on one strand (intrastrand cross-link)

These interactions may alter gene expression (see Sections Nonlethal Genetic Alterations in Somatic Cells and Carcinogenesis and Molecular Mechanisms of Malignant Transformation and Tumor Formation). The changes in gene expression may be quantitative, that is, formation of the wrong amount of a protein in an inappropriate time period of cellular life, or qualitative, that is, formation of a protein with altered or impaired properties. In both cases, the changes may cause the death of the cell. However, interaction of xenobiotics with nucleic acids is more important in generating somatic mutations which can be the initiating event for a process ultimately leading to malignant transformation of cells and tumor growth. Alkylation of the O-6 position of guanine appears important in the mutagenicity and carcinogenicity of nitrosamines and other chemicals that readily form methyl carbonium ions. In addition, other sites such as the N-7, N-2, and C-2 positions of guanine may also play an important role in DNA adduct formation with other electrophilic chemicals. Ribonucleic acid (RNA) also contains nucleophilic sites, and thus critical intracellular functions of RNA such as protein synthesis may be perturbed by covalent interaction of electrophilic chemicals with RNA.

3.4. Perturbation of Calcium Homeostasis by Xenobiotics or their Metabolites

Intracellular calcium concentrations are rigorously maintained at around 10^{-7} M against an extracellular concentration of more than 10^{-3} M. Three principal buffer systems are important in maintaining this steep gradient in virtually all cells: the plasma membrane, the mitochondria, and the endoplasmic reticulum. All systems require ATP to transport calcium, directly or indirectly. Exposure of freshly isolated or cultured cells to numerous toxins such as *tert*-butyl hydroperoxide, quinones, paracetamol, and carbon tetrachloride induces a rapid and sustained rise in cytosolic calcium concentrations, which correlates well with the subsequent loss of cell viability [138, 139]. Prevention of this rise by omitting calcium in the extracellular buffer or by addition of calcium chelators may prevent cell death. A central event in calcium-induced toxicity is the activation of calcium-dependent degradative enzymes such as proteases, phospholipases, and endonucleases (Fig. 51).

Figure 51. Increased concentrations of intracellular calcium may activate calcium-dependent degradative enzymes, resulting in the destruction of proteins and lipids and in DNA fragmentation, thus causing cell death

Cytoskeletal integrity is important for a number of cellular functions including motility, shape, secretion, and division. Activation of calcium-dependent proteases results in disruption of cytoskeletal components and formation of plasma membrane blebs (protrusions). In addition, activation of calcium-dependent phospholipases may induce membrane phospholipid breakdown, and calcium-dependent endonucleases may lead to DNA fragmentation by the formation of DNA double-strand breaks. These toxic biochemical cascades may act in concert to cause cell death [104].

3.5. Nonlethal Genetic Alterations in Somatic Cells and Carcinogenesis

The induction of cancer by chemicals is a complex multistep process involving interactions between environmental and endogeneous factors. Tumors are formed as a result of aberrant tissue growth due to loss of control mechanisms of cell division. A model traditionally used for an operational description of carcinogenesis is the initiation–promotion model. Initiation, the first stage, requires a genotoxic event such as binding of an electrophilic xenobiotic to DNA causing a premutagenic lesion in a single cell [140, 141]. After DNA replication, the premutagenic lesion may be transformed into a heritable mutation (i.e. by base-pair substitution; see Section Molecular Mechanisms of Malignant Transformation and Tumor Formation). In the promotion stage, several, primarily nongenotoxic, mechanisms facilitate (promote) the preferential proliferation of the initiated cell and finally resulting in the formation of a tumor. Initiators are usually genotoxic agents, whereas promoters generally act by interfering with extranuclear sites and processes; most promoters increase cell growth and cell proliferation.

In contrast to initiators, which are believed to result in irreversible changes in the cellular genome without thresholds, promoters show some reversibility, and thresholds for promoters can be discussed. This stepwise nature of carcinogenesis was first shown in mouse skin, and this model has now been well characterized (Fig. 52). In a typical experiment, an initiating chemical such as dimethylbenzanthracene is applied to mouse skin at a low dose so that very few tumors, if any, are produced in the animals lifetime. After an interval of one week to one year, the treated (initiated) skin is exposed to multiple applications of a promoter such as the phorbol esters found in croton oil. Tumors begin to appear within 5 to 6 weeks after application of the promotor, and all mice carry tumors by 10 to 12 weeks after the start of application (Fig. 52).

Figure 52. Schematic presentation of the initiation – promotion model of chemical carcinogenesis in the mouse skin

Promoters reduce the latency period and increase the number of tumors only when applied after the initiator (3, 4). The application frequency required for promoting effects to occur depends on the initiating carcinogen and the target tissue. If the application frequency of the promoter is too low, the promoting effects are not observed (i.e., no tumors are formed or the tumor yield is not increased, 5). This is also the case, when the promoter is applied prior to the initiator (6) or alone without initiating agent (7). Tumors can also be produced by the initiating agent alone if it is applied at sufficient concentration or above a certain application frequency (1). In this case, the initiator is termed a complete carcinogen.

The initiation–promotion experiments on mouse skin and similar experiments in the rodent liver have led to the following general rules of carcinogenesis:

1. The initiator must be given first; no tumors or very few tumors result if the promoter is given first.
2. The initiator, if administered once at a subcarcinogenic dose, does not produce tumors during the time of observation; however, repeated doses of the initiator may cause tumors even in the absence of the promoter (the initiator is a complete carcinogen in this case).
3. The action of the initiator is irreversible; tumors result in nearly the same yield if the interval between initiation and promotion is extended from one week to one year.
4. The initiator is an electrophile, or is bioactivated to an electrophile, which binds covalently to DNA causing a mutation after DNA replication.
5. In contrast, there is no evidence of covalent binding of promoters or their metabolites to DNA.
6. The action or the promoter is reversible at an early stage and usually requires repeated exposure; thus, there is probably a threshold level of exposure to promoters. However, threshold levels can not be reliably defined, as long as the biochemical mechanism involved in tumor promotion is not precisely known. In contrast to the established target of the initiation process (DNA), the molecular mechanisms of tumor promotion are still largely unknown.

In addition to promotion of skin carcinogenesis by the phorbol esters, there are known or suspected promoters for tumors in other organs [142, 143]. Bile acids are known to be promoters of colon carcinogenesis in experimental animals. In humans, there is a strong association between high intake of dietary fat and cancer of the colon; since ingestion of fat increases the amount of bile acids in the colon, the increased incidence of colon cancer may be due to the promoting effect of the bile acids on intestinal epithelia. In rat bladder, saccharin and cyclamate are promoters for tumors initiated by a single dose of dimethylnitrosourea; tryptophane is a promoter for urinary bladder tumors in dogs treated with an initiating dose of 4-aminobiphenyl or 2-naphthylamine. Hormones are also known modifiers of chemical carcinogenesis. Oral or intravenous administration of dimethylbenzanthracene produces mammary tumors in susceptible female mice. Prolactin will increase and accelerate tumor development, whereas ovariectomy results in reduced tumor yield.

In addition to these two stages a third stage, termed progression, has since been established as an integral part of the carcinogenic process. In this last stage additional mutational events increase the malignancy of the tumor, that is, the tumor grows in an invasive manner, destroying the surrounding tissues and forming metastases in other organs (Fig. 53).

Figure 53. Multistep model of tumor formation

Genotoxic events resulting in heritable mutations cause the formation of an initiated cell (initiation). In the following stage of promotion, nongenetic (epigenetic) events contribute to preferential proliferation of the initiated cell. In the third stage of progression, additional genetic events increase the malignancy of the tumor tissue (i.e., its growth becomes increasingly destructive and metastases are formed in other organs).

The understanding of the molecular mechanisms on route from DNA interactions to a clinically observable tumor requires some knowledge on the basic roles of DNA biochemistry and biology in cellular function and replication. Therefore, a short chapter on DNA biochemistry and biology follows. Further and in-depth information is presented in textbooks on biochemistry and molecular biology.

3.6. DNA Structure and Function

3.6.1. *DNA Structure (* ⟶ Nucleic Acids – Structure of DNA*)*

With the exception of certain viruses, the genetic information of all cells is contained in deoxyribonucleic acid (DNA), whose structure and constituents permit the accurate storage of a vast amount of information. In the cell nucleus, the DNA is packaged with proteins to form chromatin.

The genetic code of the DNA is denoted by four letters: two pyrimidine nitrogenous bases, thymine (T) and cytosine (C), and two purine bases, guanine (G) and adenine (A). These are are functionally arranged in codons (or triplets). Each codon consists of a combination of three letters and codes for a specific amino acid.

The bases on one strand are connected together by a sugar (deoxyribose) phosphate backbone. DNA can exist in a single-stranded or double-stranded form. In the latter state, the two strands are held together by hydrogen bonds between the bases. The adenine on one strand binds to thymine on the sister strand, and guanine pairs with cytosine. Two hydrogen bonds are involved in the binding between adenine and thymine, while three hydrogen bonds are involved in the binding of guanine to cytosine.

Double-stranded DNA has the unique property that it can make identical copies of itself when supplied with precursors and the required enzymes. In simplified terms, two strands begin to unwind and separate as the hydrogen bonds are broken. This produces single-stranded regions. Complementary deoxyribonucleotide triphosphates then pair with the exposed bases under the control of the enzyme DNA polymerase.

The information in DNA is assembled in structural genes. A structural gene is a linear sequence of codons, which contain the information for a functional protein, consisting of a sequence of amino acids. Individual proteins may function as structural components of the cell, as enzymes, or may regulate important cellular functions. The DNA of eukaryotic cells contains repeated sequences of some genes. Also, eukaryotic genes, unlike prokaryotic (i.e., bacterial) genes, have noncoding DNA regions called introns between coding regions known as exons. This property means that eukaryotic cells have an additional processing mechanism at transcription.

3.6.2. *Transcription (* ⟶ Nucleic Acids – Transcription*)*

The linkage between the DNA in the nucleus and proteins in the cytoplasm is not direct (Fig. 54). The information contained in the DNA molecule is transferred to the protein-synthesizing machinery of the cell via another informational nucleic acid, called messenger RNA (mRNA), which is synthesized complementary to the relevant DNA sequence by RNA polymerase. Although similar to DNA, mRNAs are single-stranded, and contain the base uracil instead of thymine, and ribose instead of deoxyribose. The mRNA molecules act as transport vehicles for the information contained in the genes being expressed.

Figure 54. Scheme of the important steps in gene transcription and protein synthesis

In eukaryotic cells, the initial mRNA copy contains homologues of both the intron and exon regions. The intron regions are then removed and the exon regions are spliced together to form the active mRNA molecules, which are then transported through the pores of the nuclear membrane to the cytoplasm.

3.6.3. *Translation (* ⟶ Nucleic Acids – Translation*)*

The next process involves the translation of mRNA molecules into polypeptides. This procedure requires many enzymes and two further types of RNA: transfer RNA (tRNA) and ribosomal RNA (rRNA). There is a specific tRNA for each amino acids. The tRNA molecules are involved in the transport and coupling of amino acids into the resulting polypeptide (Fig. 54). Each tRNA molecule has two binding sites, one for the specific amino acid, the other containing a triplet of bases (the anticodon) which is complementary to the appropriate codon on the mRNA.

The rRNA is complexed with protein to form subcellular globular organelles called ribosomes. Ribosomes can be regarded as the reading heads, which allows the linear array of mRNA codons each to base-pair with an anticodon of an appropriate incoming tRNA amino acid complex.

3.6.4. *Regulation of Gene Expression*

All cells possess the same genetic information, but different types of cells exhibit distinct gene transcription patterns. These differences in gene expression are critical to the morphological and biochemical properties of the many thousands of cell types of the human and animal body. Hence, mechanisms are required that regulate gene expression, that is, determine which genes are expressed and to what extent and which genes are not expressed in a certain cell type at a particular time. The mechanisms involved in regulation of gene transcription are not entirely understood. The transcription of structural genes is regulated by a special set of codons, in particular, promotor sequences, the initial binding sites for RNA polymerase before transcription begins. Different promoter sequences have different affinities for RNA polymerases. Additional regulatory genes called operators regulate the activity of several genes or gene groups (operons). The activity of the operator itself is further controlled by a repressor protein, which stops the transcription of the whole operon by binding to the operator sequence. Due these regulatory mechanisms cells are able to express only the genes required at a given moment for their specialized function. This not only helps to conserve cellular energy, but is also critical for correct cellular differentiation, tissue pattern formation and function, and maintenance of the physiological integrity of the entire organism.

3.6.5. *DNA Repair*

All living cells possess several efficient DNA repair processes. DNA repair is crucial in protecting cells from spontaneous and exogenous lethal and mutating effects such as heat-induced DNA hydrolysis, UV radiation, ionizing radiation, DNA-reactive endogenous chemicals, free radicals, and reactive oxygen species. Among the various DNA repair mechanisms, the most comprehensively studied mechanism in eukaryotes is the excision repair pathway. This mechanism involves a group of enzymes acting cooperatively to recognize DNA lesions, remove them, and correctly replace the damaged sections of DNA.

The excision repair pathway is regarded as error-free and does not lead to the generation of mutations. However, this pathway may become saturated after excessive DNA damage. In this case, the cell may be forced to activate other repair mechanisms which do not operate error-free. Several of these mechanisms, such as error-prone repair, have been well characterized in bacteria, but their counterparts, if any, in mammalian cells have not been identified yet.

3.7. Molecular Mechanisms of Malignant Transformation and Tumor Formation

3.7.1. *Mutations*

Mutations are hereditary changes in genetic information, resulting from spontaneous or xenobiotic-induced DNA damage. The term mutation can be applied to point mutations, which are qualitative changes involving one or a few bases within one gene, and to larger changes involving parts of the chromosome detectable by light microscopy or even whole chromosomes and thus many thousands of genes (Table 22).

Table 22. Types of mutations

Gene mutations	base-pair substitutions, deletions, insertions, gene rearrangements, gene amplifications
Chromosomal mutations	
Structural	breaks, translocations
Numerical	loss or gain of an entire chromosome

Point mutations can occur when one base is substituted for another (base substitution) or when base pairs are deleted or inserted (deletions/insertions). Substitution of another purine for a purine base or of another pyrimidine for pyrimidine is called a transition, while substitutions of purine for pyrimidine or pyrimidine for purine are called transversions. Very small alterations in the chemical structure or the DNA bases may be sufficient for a base-pair substitution to occur. Guanine, for example, normally pairs with cytosine, while O^6-methylguanine (a frequent DNA modification seen with methylating agents such as dimethylnitrosamine) pairs with thymine (Fig. 55).

Figure 55. Formation of a base substitution

Guanine normally pairs with cytosine and adenine with thymine (upper part); in contrast, O^6-methylguanine (a frequent DNA modification induced by methylating agents such as dimethylnitrosamine) pairs with thymine (lower part), resulting in a hereditary change of the genetic information

These changes in certain codons may cause insertion of the wrong amino acid into a relevant polypeptide. In this case, the changes are named missense mutations. Such proteins may have dramatically altered properties if the new amino acid is close to the active center of an enzyme or affects the three-dimensional structure of an enzyme or a structural protein. Hence, the alterations may result in marked changes in the differentiation and proliferative characteristics of the affected cells. A base substitution can also result in the formation of a new inappropriate stop (or nonsense) codon. The result of nonsense mutations is the formation of a shorter and, most likely, inactive protein. Owing to the redundancy of the genetic code, about a quarter of all possible base substitutions will not result in amino acid replacement and will be silent mutations.

Bases can be also deleted or added to a gene. As each gene is of a precisely defined length, these changes, if they involve a number of bases that is not a multiple of three, result in a change in the reading frame of the DNA sequence and are known as frameshift mutations. Such mutations often have a dramatic effect on the polypeptide of the affected gene, as most amino acids will differ from the point of insertion or deletion of bases in the DNA strand onwards.

Some forms of unrepaired alkylated bases are lethal due to interference with DNA replication. Others, such as O^6-methylguanine lead to mutations if unrepaired. These differences indicate that not all DNA adducts are of equivalent importance. In fact, some adducts appear not to interfere with normal DNA functions or are rapidly repaired, others are mutagenic, and yet others are lethal. The most vulnerable base is guanine, which can form adducts at several of its atoms (e.g., N-7, C-8, O-6 and exocyclic N-2, see Section Interaction of Reactive Intermediates with Cellular Macromolecules).

Intrastrand and Interstrand Cross-Links. Xenobiotics with bifunctional alkylating properties can also form links between adjacent bases on the same strand (intrastrand cross-links) or between bases on different strands (intrastrand cross-links). The induction of frameshift mutation does not necessarily require formation of covalent adducts. Some compounds that have a planar structure, particularly polycyclic aromatic hydrocarbons, can intercalate between the strands of the DNA double strand. The intercalated molecules may interfere with DNA repair or replication and cause insertions and/or deletions of base pairs. The precise molecular event is still unclear, although several mechanisms have been proposed. Hot spots for frameshift mutations often involve sections of the DNA strand taht contain a run of the same base (e.g., the addition of a guanine to a run of six guanine residues).

DNA strand breaks result from the hydrolysis of the sugar–phosphate bond or a nucleotide. In a double-strand, both a single- and double-strand breaks may occur. DNA strand breaks are often induced by hydroxyl radicals, which are formed at high rates both spontaneously during normal cell life and in the presence of exogenous chemicals. AP lesions (apurinic/pyrimidinic sites) in the DNA strand result from spontaneous hydrolysis of the glucosidic bond and loss of the DNA base (see Fig. 37). Similar to the situation with DNA strand breaks, AP lesions are a common spontaneous event; however, the hydrolysis can be dramatically increased by various types of DNA adducts, such as N^7-substituted purines, a common target of alkylating chemicals (see Section Interaction of Reactive Intermediates with Cellular Macromolecules). Another common spontaneous event is the desamination of cytosine to uracil (Fig. 56); approximately 100 desaminations take place in each cell every day (⟶ Nucleic Acids – Transcription).

Figure 56. Deamination of cytosine to uracil

dR = Deoxyribose

3.7.2. *Causal Link between Mutation and Cancer (see also, ⟶ Carcinogenic Agents ; ⟶ Mutagenic Agents)*

The change from cells undergoing normal, controlled cell division and differentiation to cells that are transformed, divide without control, and are undifferentiated or abnormally differentiated does not occur in a single step. Malignant transformation is a multistage process. Evidence for the involvement of multiple stages comes from in vitro studies, animal models, and epidemiological observations. In humans, the latent period between exposure to a chemical carcinogen and the appearance of a tumor in the target tissue is approximately 10–25 years. Modern molecular-biology techniques enable thorough investigations of the genome of malignant cells in comparison with the genome of their normal counterparts. These studies clearly show that a single mutation is not sufficient to induce malignant transformation. The number of genetic changes varies between two and seven in different tumor types. Also, several types of mutations are usually formed in a malignant transformed cell (i.e., base-pair substitutions, gene rearrangements, chromosomal breaks, and deletions.

3.7.3. *Proto-Oncogenes and Tumor-Suppressor Genes as Genetic Targets*

Why should mutations be causally linked to cancer? The answer to this question has increasingly become clear since the 1980s with the study of proto-oncogenes and tumor-suppressor genes [144, 145]. It is now appreciated that normal control of cell division and differentiation is based on the interplay of two sets of genes, the proto-oncogenes and the tumor-suppressor genes. Abnormal activation of proto-oncogenes and/or inactivation of tumor-suppressor genes eventually leads to malignant transformation.

Oncogenes were originally discovered in the genome of transforming retroviruses and were therefore named v-oncogenes [144, 146]. Subsequent studies showed that these viral genes were originally derived from the mammalian genome. In the normal cell, these proto-oncogenes have important functions in signal transduction

pathways.

3.7.4. *Genotoxic versus Nongenotoxic Mechanisms of Carcinogenesis*

Oncogene activation and tumor-supressor gene inactivation induced by mutations provide strong evidence for the involvement of genotoxic mechanisms in tumor formation. However, it has been recognized for many years that cancers can arise without direct or indirect interaction between a chemical and cellular DNA, that is, in the absence of direct mutations. The distinction between nongenotoxic and genotoxic carcinogens was more sharply defined following the identification of a comparatively large number of nongenotoxic carcinogens by the U.S. National Toxicology Program [147]. These include a wide range of chemicals acting by a variety of mechanisms, such as disruption of normal hormonal homeostasis in hormone-responsive tissues, and peroxisome proliferation and proliferation of urothelial cells of the urether and urinary bladder following damage by kidney stones.

Genotoxic carcinogens tend to induce tumors in several tissues of both males and females in both rats and mice. In contrast, nongenotoxic carcinogens usually induce tumors only at high doses, in one tissue, in one sex, or only in one species. The experimental evidence available so far does not support the existence of real thresholds for DNA-reactive carcinogens, although very low concentrations may exist for which practically no clinically manifest tumors may be observed in the animal (or human) lifespan. However, these concentrations can not be considered as thresholds. In the case of carcinogens that operate via other biological effects, the carcinogenic activity would parallel dose–response relationships of the relevant biologic effects, a very important aspect for human risk assessment. Treatment regimens or exposure scenarios that do not elicit biological effects would not promote tumor formation. There are, however, two major problems: very few dose–response studies have been performed with nongenotoxic carcinogens, and in most cases the biochemical mechanisms responsible for the tumor promoting action are not understood.

Usually, non-enotoxic carcinogens are divided into two major categories. The first includes compounds that induce cytotoxicity and regenerative cell proliferation, e.g., 2,2,4-trimethylpentane and other branched-chain hydrocarbons in the proximal tubules. The second group of nongenotoxic carcinogens induce cell proliferation in the absence of cytotoxicity (they are directly mitogenic), relevant examples in this group are carcinogenic hormones or peroxisome proliferators such as di(2-ethylhexyl) phthalate and clofibrate. Induction of cell proliferation is involved in both categories of nongenotoxic carcinogens and may contribute to malignant transformation by increasing the number of spontaneous genetic errors, since DNA replication does not occur with 100% fidelity. Furthermore, in rapidly proliferating cells, DNA damage has a higher chance of being converted to heritable mutations. However, in all these cases cell proliferation is the final result of an as-yet unidentified molecular mechanism.

Genotoxic and nongenotoxic mechanisms are not mutually exclusive events. Rather, they cooperate in tumor formation, as can be seen with many genotoxic carcinogens. In most cases genotoxic carcinogens induce tumors only after applications of high doses, concomitantly causing cytotoxicity, cell death, and regenerative proliferation. Hence, a tumor is the final outcome of a complex, multistep interplay between genotoxic and extranuclear events.

3.8. Mechanisms of Chemically Induced Reproductive and Developmental Toxicity

The term reproductive toxicity covers any detrimental effect on the male and female reproductive system due to exposure to toxic chemicals. Developmental toxicity refers to detrimental effects produced by exposure to developing organisms during embryonic, fetal, and neonatal stages of development.The main phases of reproduction are listed below:

Germ cell production

Spermatogenesis (man)
Oogenesis (woman)

Preimplantation phase

Fertilization
Formation of the blastocyst
Implantation

Embryonic phase

Organogenesis (in humans the first 12 weeks, in rat the first 2 weeks of gestation)

Fetal phase

Functional maturation and growth of the organs, in humans week 12 to 30

Peri- and postnatal phase

Last week of gestation, birth and first period after birth

Such effects can be irreversible or reversible. Embryolethal effects are incompatible with survival and result in resorption or spontaneous abortion. Irreversible effects that are compatible with survival may cause structural or functional abnormalities in the offspring, and these are called teratogenic. Embryotoxic chemicals may also cause overall growth retardation or delayed growth of certain organs.

3.8.1. *Embryotoxicity, Teratogenesis, and Transplacental Carcinogenesis*

For an agent to be classified as a developmental toxicant, it must be harmful to the developing organism at exposure levels that do not induce severe toxicity in the mother, such as substantial reduction in weight gain, persistent emesis, or convulsions. Adverse effects on the developing organism under severe maternal toxicity may be secondary to perturbations in the maternal system. For practical purposes, however, the test compounds can be initially administered at maternally toxic doses to determine the threshold level for adverse effects on the offspring. At these exposure levels conclusions can be qualified to indicate that adverse effects of the conceptus were obtained at maternally toxic exposure levels, and may not be indicative for selective developmental toxicity.

The susceptibility of the developing organism to xenobiotic insults varies dramatically within the narrow time span of the major developmental stages (the preimplantation, embryonic, fetal, and perinatal periods), because developing organisms undergo rapid and complex changes within this short period. The major morphogenic events occuring during preimplantation development are formation of a compact mass of cells (the morula) and of the blastocyst. The latter already exhibits a certain degree of cellular differentiation. Considerable similarity exists in the timing of preimplantation development across several mammalian species, regardless of the total length of gestation [148]. At the time of blastocyst formation, cell division and metabolic capacity increase dramatically. During the preimplantation period, biochemical changes under progesterone and estrogen control render the endometrium sensitive to the blastocyst implantation. One important sign of blastocyst implantation is a prostaglandin-dependent increase in endometrial vascular permeability. Alterations in the hormonal milieu or direct excretion of specific xenobiotics into the uterine epithelia during this period can impair implantation and cause embryolethality. Limited data suggest that the preimplantation embryo appears to be susceptible to lethality but rarely to induction of structural aberrations (teratogenicity) with chemical insults. Sublethal exposures of preimplantation embryos have not yet been adequately explored.

Following implantation, organogenesis takes place, which is characterized by the division, migration, and association of cells into primitive organs. The most characteristic susceptibility of the embryo to xenobiotics during the organogenesis period is the induction of structural birth defects (terata). Within the organogenesis period (embryonic period), individual organ systems possess highly specific periods of vulnerability to teratogenic insult (Fig. 57). Administration of a teratogen on day 9 of rat gestation would result in a high level of brain and eye defects, while on day 15 structural abnormalities of the kidney and urinary bladder would predominate. As shown in Figure 57, critical periods for the susceptibility of different organs overlap, so that exposure to teratogens usually results in a spectrum of more or less severe malformations in a number of organ systems [149].

Figure 57. Degree of susceptibility of various organ rudiments of the developing organism to teratogenic xenobiotics (data from [144])

a) Eye; b) Brain; c) Heart and axial skeleton; d) Palate; e) Urogenital system

The critical phase for inducing anomalies in individual organ systems may be as short as one day or may extend throughout organogenesis. Urogenital defects, for example, can result from drug treatment from day 9 to 16 of gestation in the rat. However, the structural defects of the urogenital system depend upon the day(s) of exposure to the teratogenic antibiotic. The development of the urogenital system is multiphasic, and individual stages may have different sensitivities to chemical insult. The mechanisms governing embryonic differentiation are not well understood, but they are certainly involved in intrinsic susceptibility of individual organs to teratogenic insult.

Functional maturation and growth are the major processes occurring after organogenesis, during the fetal and perinatal periods. Insult at these late developmental stages leads to growth retardation or to more specific functional (but not structural) disorders and transplacental carcinogenesis. The fetal and perinatal period of life is highly susceptible to carcinogenesis, due to the high cellular replication rates, presence of xenobiotic biotransforming enzymes in the fetus, and immaturity of the immune system in the developing organism. Several childhood tumors occur so early after birth that prenatal origin is considered likely. These include acute lymphocytic leukemia, Wilms tumor (nephroblastoma), and neuroblastoma. Studies with direct-acting transplacental carcinogens such as ethylnitrosourea indicate that susceptibility to carcinogens begins after completion of the organogenesis period in rodents. Tumors in offspring occurred primarily when ethylnitrosourea was given during the fetal period, whereas birth defects and embryolethality predominated with exposures in the embryonic phase [150, 151]. However, this does not imply that teratogenesis and carcinogenesis are mutually exclusive processes. Teratogenesis and carcinogenesis can be regarded as graded responses of the embryo to injury, with teratogenesis representing the more gross response involving major tissue necrosis in early, relatively undifferentiated embryos, combined carcinogenicity–teratogenicity damage in older embryos, and finally, carcinogenicity alone in the fetus.

3.8.2. *Patterns of Dose–Response in Teratogenesis, Embryotoxicity, and Embryolethality*

The major toxic effects of prenatal exposure observed at the time of birth are embryolethality, malformations, and growth retardation. The relationship between embryolethality, malformations, and growth retardation is quite complex and depends on the type of agent, the time of exposure, and the dose. Some developmental toxins may cause malformations of the entire litter at exposure levels that do not cause embryolethality (Figure 58). If the dose is increased, embryolethality can occur, often in combination with severe maternal toxicity. Malformed fetuses are often more or less retarded in growth, and the curve for growth retardation is often parallel to and slightly displaced to the right from the curve for teratogenicity. Such a pattern of response is indicative of agents with high teratogenic potency.

Figure 58. Possible dose – response relationship of teratogens.

A) Teratogens interfering with specific events in differentiation; B) Teratogens acting via general cytotoxicity and induction of cell necrosis

A more common dose–response pattern involves embryolethality, malformations, and growth retardation of surviving fetuses. Exposure to these chemicals results in a combination of resorbed, malformed, growth-retarded, and “normal” fetuses. Depending on the teratogenic potency of the agent, lower doses may cause predominantly malformations. As the dosage increases, however, embryolethality predominates until the entire litter is resorbed. Growth retardation can precede both these outcomes or parallel the teratogenicity curve.

A third dose–response pattern consists of growth retardation and embryolethality without structural abnormalities. Growth retardation of surviving fetuses usually precedes significant embryolethality. Agents producing this pattern of response would be considered embryotoxic but not teratogenic, and are also toxic to the maternal organism. In contrast, potent and specific teratogens often show only weak toxicity to the maternal organism.

The best known example is the hypnotic sedative thalidomide, which was rarely associated with severe undesired effects in adult humans but induced malformation in thousands of children whose mothers had taken the drug as a sleeping aid at the recommended therapeutic doses during gestation. The existence of these three general patterns of response indicate that for some agents embryolethality and teratogenicity are different degrees of manifestations of the same primary insult. For other agents, there is a qualitative difference in response, and the primary insult leads to embryotoxicity and embryolethality alone.

For practical purposes (for exact experimental procedures, see Section Embryotoxicity and Teratogenicity) a relatively small number of pregnant rodents (approximately eight per group) are exposed on days 6 through 15 of gestation to the test agent at doses up to those causing limiting maternal toxicity and/or severe embryotoxicity (death, severe growth retardation). The purpose of this dose-range finding study is to obtain a qualitative yes/no signal about the potential developmental toxicity of the agent, and information on doses causing severe impairment of the maternal organism. For the main evaluation of developmental toxicity the highest dose should cause measurable but slight maternal toxicity (i.e., significant depression of weight gain) or embryotoxicity (i.e., significant depression of fetal body weight, increased embryolethality, and/or structural malformations), and the low dose should cause no observable effects.

[Top of Page]

4. Methods in Toxicology

4.1. Toxicological Studies: General Aspects

The aim of toxicology is the assessment and management of potential hazards from exposure of humans and the general environment including animals and plants to chemicals. To achieve this objective, detailed knowledge on the inherent hazard of a xenobiotic (for definition, see Section Hazard Identification Techniques), that is, its acute and chronic toxicity, its no observed effect level (NOEL), and its teratogenic, mutagenic and carcinogenic effects, is required. This information can not be obtained from a single experiment. A battery of in vivo and in vitro toxicity tests must be utilized. As required by law in most industrialized countries, all toxicity testing must be performed under the rules of good laboratory practice with exact documentation of all relevant conditions and results. Adequate planning of toxicity tests for obtaining optimal information from the experiments may greatly improve the basis for the risk assessment of a chemical and may reduce the number of animals needed and the financial expense associated with toxicity studies. Therefore, all test batteries should be part of an integrated approach to toxicity studies and include not only methods to determine the toxic effects of a chemical and their dose dependence, but also toxicokinetics, biotransformation, and mechanisms of action. This chapter provides an overview of the currently used methods for the assessment of a chemical's toxic profile. For details, specific guidelines on practical aspects of toxicity studies and types of data required can be obtained from web sites of national and international organisations (see Section Information Resources). OECD guidelines for the toxicity testing of chemicals in vivo are listed in Table 23.

*Date of deletion.

For the evaluation of a new chemicals toxic effects in laboratory animals two types of studies are carried out: acute-toxicity and repeated-dosing studies.

Acute Toxicity. Following administration of a single dose of the test substance or of multiple doses given over a period of up to 24 h, potentially adverse effects are usually monitored during the following 14 d. Acute toxicity studies in animals aim to assess the human risk from single exposure to high doses, for example, in industrial accidents, after drug overdoses, or after suicide attempts.

Repeated-Dosing Studies: Subacute, Subchronic, and Chronic Toxicity. The purpose of repeated daily doses of a chemical for part of the animal's life span is to study subchronic and chronic effects. Studies on *subacute toxicity* are carried out for two to four weeks, while studies on *subchronic toxicity* usually last for a period of three months. These studies are helpful in assessing the human risk resulting from frequent exposure to household or workplace chemicals and from intake of chemicals used for therapeutic purposes. Studies to determine *chronic toxic effects* are carried out for at least six months; studies aiming to investigate the carcinogenic effects of a test compound are carried out over the animal's entire lifetime. Lifetime exposure of humans may occur to widespread environmental pollutants, food additives, or residues of agricultural chemicals in food.

In addition to the acute and repeated-dose toxicity studies, the reproductive and developmental toxicity as well as the genotoxicity of a new chemical must be investigated in separate experiments.

Many thousands of new and potentially toxic compounds are synthesized every year. It would be a waste of money, resources and manpower if the entire battery of toxicity tests were automatically performed for every new chemical. Therefore, toxicity testing is rather undertaken on the basis of a decision-point approach in several stages, as shown in Figure 59. At the end of every stage, the decision must be met, if the development will be continued or if, on the basis of the toxicity data available so far, the potential human risk of the exposure to this chemical is unacceptable. If the latter is true, the development and consequently the toxicity testing is stopped.

Figure 59. Evaluation of the toxicity profile of a new chemical compound on the basis of a decision point approach

At every step of toxicity testing, further development may be interrupted if, on the basis of data collected up to that point, the human risk is considered unacceptable.

Animal Husbandry. The use of standardized conditions for the housing of animals plays a major role in the planning, evaluation, and interpretation of toxicity tests. Animals must be kept in a controlled environment, i.e., constant temperature of 22 ± 3 °C, sufficient ventilation, relative humidity between 30 and 70% and a 12 h light/dark cycle. Diet composition and quality of drinking water must also be standardized and controlled throughout the experiment. Only healthy young adult animals should be enrolled in the studies, and the animals should be allowed to acclimatize to the experimental conditions for at least one week prior to first dosing. After the acclimatization period, animals with poor health or body weights varying by more than 20% of the the group's mean body weight are either excluded from the studies or randomized to ensure a homogenous population in the different control and treatment groups. The basic guidelines — choice of species, number of animals, dosing regimens, duration and frequency of observation, assessment of specific body functions — for acute, subchronic and chronic toxicity tests are summarized in Table 24.

Table 24. Basic guidelines for acute, subchronic, and chronic oral toxicity tests

	Acute oral	Subchronic oral	Chronic oral
Animals	rats preferred	rodent and nonrodent species	rodent and nonrodent species
Sex		males and females equally distributed per dose level	
Age	young adult, weight variation within 20 % of mean	rodents, 6 weeks; dogs 4 – 6 months old	
Number of animals	at least 10 (5 per sex)	at least 20 for rodents (10 per sex)	50 per sex group for rodents
Number of treatment groups	3; mortality rates between 10 and 90 % should be produced	3; mortality should not exceed 10 % in high-dose group	3; low dose should reflect expected human exposure and high dose must produce not more than 10 % mortality
Untreated control	not necessary	yes	yes
Vehicle control	yes, if vehicle of unknown toxicity is used	yes	yes
Dosing	gavage; single dose, same dose of vehicle; if necessary	diet, gavage, drinking water	diet, gavage, drinking water

	use divided doses over 24 h		
Duration of study	at least 14-d observation period	90 d	6 – 24 months in rats
Body weight determination	before dosing, weekly thereafter, and at death	weekly and at termination	weekly for first 13 weeks; every 2 weeks thereafter and at termination
Necropsy	all animals	all test animals; organ weights of liver, kidney, heart, lungs, brain, gonads, adrenals, and spleen	
Histopathology	examination of organs showing evidence of gross pathological change	all tissues high-dose and control groups; liver, kidney, heart, lungs, target organs, and any gross lesion in mid- and low-dose groups	all tissues of animals
Frequency of cage-side observations	frequently during day of dosing; once each morning and late afternoon thereafter	daily	daily
Observations, assessments	nature, onset, severity, and duration of any effect observed		
		ophthalmoscopy: pretest and at termination in control and high-dose groups	
		hematology/clinical chemistry:	
		pretest, dosing midpoint, termination	pretest and at 3, 6,12, 18, 24 months
		urine analysis: dosing midpoint, termination	pretest and at 3, 6,12, 18, 24 months

A variety of in vitro methods are in development to reduce the numbers of animals used in toxicity testing. Some of the developed methods have gained regulatory acceptance, and some may be used for a priority-determining process for further testing. All well-evaluated methods focus on local effects such as skin and eye irritation, where most progress in the development of nonanimal methods has been made. Regarding replacement of toxicity studies on systemic effects after repeated exposure by nonanimal methods, due to the complexities of interactions resulting in toxic responses, acceptable nonanimal tests equaling the predictive power of animal testing are unlikely to be available in the near future.

4.2. Acute Toxicity

4.2.1. *Testing for Acute Toxicity by the Oral Route: LD_{50} Test and Fixed-Dose Method*

The objectives of acute toxicity tests are

1. To assess the intrinsic toxicity of the test compound
2. To identify target organs of toxicity affected by the xenobiotic
3. To provide information concerning the dose selection and treatment regimens for repeated-dose studies
4. To provide information for human risk assessment after a single high-dose exposure to the chemical
5. To provide essential data for the classification, labeling, and transportation of the chemical (regulatory view report)

LD_{50} Test. The determination of the mean lethal dose (LD_{50}) is still often considered as the first step in the evaluation of the acute oral or inhalation toxicity of a new chemical; with the present knowledge and recent experiences, the formal determination of the LD_{50} is no longer considered as necessary, and alternative methods that are also to be used for classification and labeling have been developed. However, since the test is still widely used, it will be briefly described before treating the newer methods used in testing of acute toxicity and the reasons that led to these changes.

In the LD_{50} test, groups of animals (usually female rats) are treated with graduated doses of the test compound, and by using mathematical models the dose which causes death in 50% or more of the population is determined. Internationally accepted guidelines recommend the use of at least three dose groups with five males and five females for each dose or the use of three dose groups with five animals of one sex and one dose with five animals of the other sex [152]. The LD_{50} is then determined from data obtained as described in Section Dose–Response: a Fundamental Issue in Toxicology. Chemicals with LD_{50} values ≤ 25 mg/kg are considered very toxic, between 25 and 200 mg/kg as toxic, and between 200 and 2000 mg/kg as harmful. Some potentials and limitations of the LD_{50} test follow:

Potential

1. Useful as a first approximation of hazards in the workplace
2. Basis for the design of subchronic studies
3. Properly conducted test may give useful information on other relevant toxicity parameters
4. Rapid completion

Limitations and Problems

1. Lethality only criterion applied, other toxic effects not considered
2. Animal welfare is major point of concern because large number of animals are required to obtain statistically acceptable values
3. Large variations in LD_{50} in different laboratories with identical chemicals, many influencing factors
4. Species and strain differences cause difficulties in extrapolation
5. No information on chronic toxicity obtained (chronic effects are more important for regulating exposure)

The scientific significance of the LD_{50} test has been repeatedly questioned, not only because the lethal dose is not relevant for human risk assessment but also on the basis of the variability of the test results and last not but least for reasons of animal welfare. Comparative assessment of LD_{50} values in 60 laboratories under controlled conditions resulted for example in considerably different LD_{50} values (by a factor of up to 14). Therefore, numerous alternatives to the LD_{50} test have been proposed for the evaluation of acute toxicity that rely on signs of toxicity rather than on mortality. One of this procedures, the fixed-dose method - has recently gained acceptance by the OECD and the EU

Fixed-Dose Method. The fixed-dose method relies on the observations of clear signs of toxicity developed at one of a series of fixed-dose levels (i.e. 5, 50, 300, and 2000 mg/kg of the chemical oper kilogram body weight). The dose levels at which signs of toxicity but no deaths are detected are used to classify the test compounds according to their toxic potential (Table 25).

Table 25. Classification of toxicity of a xenobiotic with the fixed-dose method

Dose (oral), mg/kg	Results	Classification
5	less than 90 % survival	very toxic
	90 % or more survival but evident toxicity	toxic
	90 % or more survival, no evident toxicity	retest at 50 mg/kg

50	less than 90 % survival	toxic, retest at 5 mg/kg
	90 % or more survival, but evident toxicity	harmful
	90 % or more survival, no evident toxicity	retest at 500 mg/kg
500	less than 90 % survival or evident toxicity and no death	harmful, retest at 50 mg/kg
	no evident toxicity	retest at 2000 mg/kg
2000	less than 90 % survival	harmful
	90 % or more survival, with or without evident toxicity	unclassified, does not represent a significant acute toxic risk if swallowed, no further testing necessary

As can be seen in Table 25, the fixed-dose method allows a classification identical to that previously obtained in the LD_{50} test. Moreover, comparative investigations utilizing both the LD_{50} test and the fixed-dose procedure revealed that in the majority of the test compunds (80–90%), the toxicity class assigned by determining the LD_{50} was identical to that determined by the fixed-dose method [152, 153].

In the fixed-dose method, at least ten animals (five per sex) are used for each dose investigated. The initial dose chosen (5, 50, 300, or 2000 mg/kg body weight) is one that is judged likely to produce evident toxic effects, but no mortality. When such a judgement can not be made due to lack of information on the potential toxic effects of the xenobiotic, an initial “sighting” study should be carried out. If clear signs of toxicity do not occur at the starting dose of 300 mg/kg during the two weeks observation period, the dose is increased to the next level. A careful clinical examination of the animals is performed at least twice on the day of administration and once daily thereafter for the next two weeks. Animals obviously in pain or showing severe signs of distress or toxicity are humanely killed. Cage-side examinations include skin and fur, eyes and mucous membranes, respiratory system, blood pressure, somatomotor activity, and behavior (for procedures, see Section Toxicological Evaluation of the Nervous System). Particular attention is directed to observation of tremors, convulsions, hypersalivation, diarrhoea, and coma as indices of neurotoxicity. Food consumption and weight development are also monitored constantly. At the end of the observation period, all animals in the study are killed and subjected to gross autopsy. Organs showing macroscopic evidence of gross pathology are further subjected to histopathological examination.

The fixed-dose method offers several important advantages as compared with the traditional LD_{50} test:

1. The available evidence suggest that the fixed-dose method produces more consistent results without substantial interlaboratory variation.
2. It provides information on the type, time of onset, duration, and consequences of toxic effects. This information is more relevant for assessing the risks of human exposure to the chemical than the mean lethal doses of the LD_{50} test.
3. It requires fewer animals than the LD_{50} test (roughly 50%) and subjects the animals to less pain and distress.
4. It enables the classification of chemicals according to regulatory requirements.

For the “standard” acute oral and dermal tests the LD_{50} should be determined, except when the substance causes no mortality at the limit dose (usually 2000 mg/kg). Similarly, for an acute inhalation toxicity study the LC_{50} should be determined, unless no mortality is seen at the limit concentration (5 mg per L per 4 h for aerosols and particulates, 20 mg per L per 4 h for gases and vapors). In the fixed-dose procedure, the discriminating dose (the highest of the preset dose levels which can be administered without causing mortality) should be determined. For the acute toxic class and the up-and-down methods the final dose used in the study should be determined following the testing protocol, except when the substance causes no mortality at the limit dose.

Whichever approach is used in determining acute toxicity critical information must be derived from the data to be used in risk assessment. It is important to identify the dose levels at which signs of toxicity are observed, the relationship of the severity thereof with dose, and the level at which toxicity is not observed (i.e. the acute NOAEL). However, note that a NOAEL is not usually determined in acute studies, partly because of the limitations in study design.

4.2.2. *Testing for Acute Skin Toxicity*

Irrespective of whether a substance can become systemically available, it may cause changes at the site of first contact (skin, eye, mucous membrane/gastrointestinal tract, or mucous membrane/respiratory tract). These changes are considered local effects. A distinction can be made between local effects observed after single and after repeated exposure. For local effects after repeated exposure, see Section 3.9. Only local effects after single ocular, dermal, or inhalation exposure are dealt with in this section. Substances causing local effects after single exposure can be further classified as irritant or corrosive substances, depending on the (ir)reversibility of the effects observed.

Irritants are noncorrosive substances which through immediate contact with the tissue can cause inflammation. Corrosive substances are those which can destroy living tissues with which they come into contact.

Knowledge on the dermal toxicity of a new chemical is one of the prerequisites for assessment of the risks associated with human exposure to the chemical, because skin contact may represent a very important route of exposure in the occupational setting and in the home. Testing for dermal toxicity is usually performed in rabbits. Three types of application of the test chemical are employed: nonocclusive, semiocclusive, and occlusive. The test compound is applied uniformly to the back or a band around the trunk (clipped free of hair); approximately 10% of the body surface of the animal should be covered. Solid substances are pulverized and moistened to a paste with physiological saline or another appropiate solvent whose effects have been fully evaluated prior to the skin test. For occlusive or semiocclusive testing, the application site is covered with a plastic sheet (or other impervious material) or with a porous gauze dressing, respectively. For unocclusive exposure, the application site should be as close to the head as possible to prevent ingestion of the chemical by the animal licking the site of application. The duration of exposure varies between 4 and 24 h. If no test-chemical-related toxic effects on the skin or systemic toxicity are observed up after doses of up to 2 g/kg body weight, testing at higher doses is unnecessary. At the end of the exposure period, the compound is removed with cotton wool soaked in an appropiate solvent and the skin irritation is scored according to the Draize scoring system as shown in Table 26. In addition, any adverse systemic effects caused by percutaneous absorption of the test compound are monitored.

Table 26. Evaluation of skin reactions according to the Draize scoring system

Erythema	Score
No erythema	0
Very slight erythema (barely perceptible)	1
Well-defined erythema	2
Moderate to severe erythema	3
Severe erythema (beet redness)	4
No edema	0
Very slight edema (barely perceptible)	1
Slight edema (edges of area well defined by definite raising)	2
Moderate edema (area raised ca. 1 mm)	3
Severe edema (raised more than 1 mm and extended beyond area of exposure)	4

However, substantial differences exist in skin anatomy between humans and experimental animals. In general, the penetration of chemicals through the human skin is similar to that of pig, miniature swine, and squirrel monkey and clearly slower than that of the rat and rabbit. For example, administration of the insecticides lindane and parathion to rabbit skin results in an absorption of 51.2 and 99.5% of the dose, respectively; the corresponding absorption rates for human skin are 9.3 and 9.7%.

Since the 1980s, in vitro studies using human skin samples have been increasingly conducted to estimate percutaneous absorption of chemicals. The following

experimental design is commonly used: A piece of excised human skin is attached to a diffusion apparatus that has a top chamber for the test compound, an O-ring to hold the skin in place, and a bottom chamber to collect samples for analysis. The flow of a chemical across the skin can be calculated with models based on chemical thermodynamics, taking into consideration the octanol/water partition coefficients, the saturated concentration in aqueous solution, and the molecular mass of the test compound [154]. However, for routine applications, the method has not been sufficiently evaluated.

Furthermore, an increasing number of toxicokinetic models for estimating the extent of percutaneous absorption of chemicals has appeared in the literature. Among them, a physiologically based toxicokinetic model was recently developed to describe the percutaneous absorption of volatile and lipid-oluble organic contaminants in dilute aqueous solution [155]. This toxicokinetic model considers both physiological parameters such as volumes of body compartments and blood flow rate, as well as the properties of the test compound. Presently, these models do not play a role in regular toxicity testing and are therefore not discussed in depth here.

More recently extensive progress has been also made in developing in vitro systems for evaluating the dermal irritation potential of chemicals. An overview of the systems that have been evaluated so far for a range of compounds by comparison of their predictive accuracy with animal test results is presented in Table 27 (for a review see [156]).

When evaluating these studies, attention should be given to the occurrence of persisting irritating effects, even those which do not lead to classification. Effects such as erythema, oedema, fissuring, scaling, desquamation, hyperplasia, and opacity which are not reversible within the test period may indicate that a substance will cause persistent damage to the human skin and eye.

Table 27. In vitro test systems for detection of dermal irritation potential

System	End point
Mouse skin organ culture	leakage of LDH* and GOT**
Human epidermal keratinocytes	release of labeled arachidonic acid, cytotoxicity
Cultured BHK21/C13 cells	growth inhibition, cell detachment
SKINTEX – protein mixture	protein coagulation

* LDH = Lactate dehydrogenase.
** GOT = Glutamic acid oxalacetic transaminase.

4.2.3. *Testing for Acute Toxicity by Inhalation*

Studying the toxicity of a chemical by inhalation exposure requires a considerable technological input. Therefore, inhalation exposure is usually not tested if this absorption pathway is not expected to occur because the test chemical is not volatile or the physicochemical properties of solids do not allow the generation of respirable particles. Particles with diameters greater than 100 µm are unlikely to be inhaled, because they settle too rapidly. Particles with diameters of 10–50 µm are likely retained in the nose and the upper parts of the respiratory tract, while particles with diameters of less than 7 µm can reach the alveoli of the human lung. When performing toxicity studies with inhalation exposure, the differences in respiratory physiology between humans and the small laboratory rodents must be considered. In contrast to humans, the rat is an obligate nose breather with a complex nasal turbinate structure which filters many small particles. Therefore, the upper size limit for particles reaching the alveolar region in rats is in the range of 3–4 µm in diameter.

The duration of exposure in acute inhalation studies is usually 4–6 h, and they may be performed either as whole-body or head(nose)-only procedures in specific exposure chambers. A number of important considerations should be taken into account in planning and evaluating inhalation studies. The frequently made assumption that on the basis of their physical form, gases and vapors will be absorbed uniformly throughout the respiratory tract is incorrect. Many gases or vapors, such as ammonia, formaldehyde, and sulfur dioxide have high solubility in water and are rapidly absorbed by the humid epithelial surface of the upper respiratory tract. Therefore, toxic effects observed after inhalation of this type of chemical will generally be confined to these regions, especially to the nasal passages. In contrast, chemicals with low solubility in water such as nitrogen dioxide, phosgene, and ozone will penetrate readily to the low pulmonary regions, even at relatively low concentrations in the respiratory air. In mixed atmospheres containing both a gas or vapor and particulates, the vapor or gas may be absorbed on the particulate fraction, so that the deposition pattern of the vapor or gas is governed by the size of the particulate fraction and not by the water solubility of the vapor or gas.

The inhalation exposure of experimental animals may be performed in a dynamic or static mode. In dynamic systems, the test atmosphere is continuously renewed, ensuring atmospheric stability and constant concentrations of the chemical in the gas phase. This mode of inhalation exposure is more complicated and requires larger amounts of the test chemical and suitable systems to ensure complete mixing of the continuously applied test compounds with the stream of air flowing through the exposure system (Fig. 60).

Static systems are sealed, and the atmosphere is circulated. The concentration of the chemical in the gas phase decreases during exposure due to its uptake and biotransformation by the experimental animals. Static systems are used predominantly in acute toxicity studies and in research laboratories because they are relatively inexpensive and consume only a small amount of the chemical in comparison to the amounts need to generate a dynamic exposure. In analogy to the LD_{50} values obtained in the acute oral studies the mean lethal air concentrations LC_{50} are assessed in acute inhalation studies, usually for an exposure time of 4 h (Fig. 61).

4.3. Repeated-Dose Toxicity Studies: Subacute, Subchronic and Chronic Studies

Repeated-dose toxicity studies assess the effects resulting from the accumulation of a compound or its toxic effects in the organism and, unlike acute studies, they can also reveal toxic effects that appear after a latency period. A classic example is the delayed neuropathy caused by some organophosphorous insecticides and by cresyl phosphates, which is manifested several weeks after the first administration of the test compound. In contrast to the marked clinical symptoms observed in the course of delayed neuropathy, these compounds hardly cause any acute symptoms immediately after the first administration. Hence, false negative results may be obtained if an assessment were based only acute toxicity testing. The major aims of repeated-dose toxicity studies are the identification of starting points for the extrapolations required in human risk assessment such as NOAEL and benchmark doses, and the identification of critical end points to be carried over into the risk assessment process.

Testing for subacute toxicity is usually performed over a time period of 2–4 weeks at three dose levels as an aid in selecting the dose levels for the subchronic studies. Studies to determine subchronic effects are usually performed in rats and dogs over 10% of the animals life-span (3 months in rats, 12 months in dogs). At the start of the study, rodents should be 6–8 weeks old and dogs 4–6 months old. The animal numbers enrolled are between 10 and20 rats and 6 and 8 dogs per sex per dose group. Ideally, the lowest dose of the chemical should not induce toxic effects, the intermediate dose should induce slight toxicity, and the high dose should induce clear signs of toxicity without causing death in more than 10% of the animals.

In both subchronic and chronic toxicity studies (see below), the test compound is often incorporated into the diet or added to the drinking water. Food consumption varies from weanling to maturity, with younger animals consuming more food on a bodyweight basis. Therefore, it is necessary to predict the changes in body weight and food consumption on a weekly basis and adjust the concentration of the test compound in the diet in order to ensure constant dosing throughout the study. Compounds not stable in diet or water or not accepted by the animals may also be applied by gavage. Application by gavage directly into the stomach ensures constant dosing, but gavage studies require skilled personnel, and gavage-related trauma may reduce survival in all groups. Oral application with the feed is usually

performed on a 7 days per week basis, while a 5 days per week scheme is frequently used for gavage administration, skin application, and inhalation studies.

Studies on the chronic toxicity of chemicals are usually performed for at least six months in rodents and 12 months in dogs, the chronic toxicity studies can be combined with a carcinogenicity study. Dose levels are usually selected on the basis of the results of studies on acute and subacute toxicity. The highest dose applied should be toxic, i.e., suppress body weight up to 10% (maximum tolerated dose, MTD). The two other dose-levels are usually 1/4 and 1/8 of the MTD. Xenobiotics showing no adverse effects in the short-term studies are usually tested at doses which are 100–200 times higher than the expected human exposure.

In both subchronic and chronic studies, cage-side examination and clinical chemistry are performed routinely during the test period. After termination of the study, much emphasis is placed on the histopathological evaluation of treatment-induced adverse effects

Cage-side observations during the study

1. Body weight, food and water consumption
2. Skin and fur, eyes, mucous membranes
3. Respiration and blood circulation
4. Motor activity and behavioral pattern

Clinical chemistry during the study

1. *Blood:* erythrocyte, leukocyte, and differential leukocyte counts; hemoglobin concentration; hematocrit, platelet, and reticulocyte counts; electrolytes; inorganic phosphorus and alkaline phosphatase; glucose, protein, albumin, creatinine, urea, lipids, enzymes
2. *Urine:* volume and coloration/turbidity, osmolality and pH, glucose and protein, urine enzymes and cytology

Toxicologic pathology after termination of the study and in animals dying during the study

1. Organ weights and macroscopic evaluation
2. Histopathological examination of brain, liver, kidney, spleen, testes, and every organ with macroscopic changes

4.4. Ophtalmic Toxicity

The majority of injuries to the eyes by direct contact with a chemical occur with substances which are handled in an uncontrolled manner, e.g,. by children in the home; and this type of injury is easily prevented at the occupational setting by using simple protective procedures. However, many irritant gases and vapors may also produce ophtalmic toxicity, and these toxic effects are of practical importance in occupational medicine.

The conventional in vivo eye irritation test in the rabbit was formalized by Draize some 50 years ago and still remains the only fully validated method to assess ophtalmic toxicity. Increasing criticism primarily based on the discomfort and the deliberate injury caused to the animals led to the development of several in vivo and in vitro alternative methods, which will be described at the end of this chapter.

In the conventional in vivo test the chemical (0.1 ml of liquid or 100 mg of solid chemical) is instilled into one eye of each of the test rabbits, the contralateral eye serving as control. Eyes are then examined periodically (usually after 1, 24, 48, 72 h and 7 dd) and the ocular lesions are scored essentially according to Draize et al.:

Cornea	
A) Opacity	
No opacity	0
Scattered or diffuse area, iris details clearly visible	1
Easily discernible translucent areas, iris details slightly obscured	2
Opalescent areas, iris details not visible, pupil size barely discernible	3
Opaque, iris invisible	4
B) Area of cornea involved	
One-quarter or less, but not zero	1
Greater than one-quarter, but less than half	2
Greater than half, but less than three-quarters	3
Greater than three-quarters, up to whole area	4
Corneal score = (A)×(B)×5 (maximum total score = 80)	
Iris	
A) Normal	0
Folds above normal, congestion, swelling, circumcorneal injection (any or all), iris still reacting to light	1
No reaction to light, hemorrhage, gross destruction	2
Iris score = (A)×5 (maximum total score = 10)	
Conjunctivae	
A) Vessels normal	0
Vessels definitely injected, above normal	1
Diffuse, deep crimson red, individual vessels not readily discernible	2
Diffuse beefy red	3
B) No chemosis (swelling)	0
Any swelling above normal (includes nictitating membrane)	2
Obvious swelling with partial eversion of lids	2
Swelling with lids about half closed	3
Swelling with lids about half to completely closed	4
C) No discharge	0
Any amount of discharge different from normal	1
Discharge with moistening of lids and hairs adjacent to lids	2
Discharge with considerable moistening around eyes	3
Conjunctival score = [(A) + (B) + (C)]×2 (maximum total score = 20)	
Total maximum score (cornea + iris + conjunctiva) = 110	

There is increasing evidence that a volume of 0.01 ml of liquid xenobiotics is as sensitive as the conventionally used 0.1 ml and is probably more appropiate for comparison with human exposure situations. Ocular toxicity testing for exposure to gases, vapors, and aerosols is carried out in appropiate exposure chambers.

A number of in vivo and in vitro alternatives to the conventional eye irritation test have been suggested. The in vivo alternatives aim at reducing discomfort of the animals by employing lower doses of the test material and increasing the sensitivity of the test by using noninvasive objective measurements. Among them, the assessment of corneal thickness and of the intravascular pressure seem to be sensitive parameters to identify mild to moderately irritant chemicals. In spite of the large number of suggested in vitro tests, currently no single in vitro test has proved effective in predicting the eye irritation. Therefore, in vitro tests can not replace the rabbit eye test yet. However, in vitro assays are useful as screens for product development to reduce the number of tests performed in animals later. A number of these tests are presented in [157]

4.5. Sensitization Testing

Chemicals that have the potential to elicit allergic reactions are continously introduced into the human environment. Therefore, allergic reactions of the skin are becoming an increasingly important problem, especially in the workplace. Allergic contact dermatitis is one of the most common occupational diseases and may become debilitating unless the causative agent is identified and exposure stopped. While irritant dermatitis is generally produced by direct interaction of the chemical with skin constituents, allergic dermatitis is the result of a systemic immune reaction which in turn induces effects in the skin. An important characteristic of allergic reactions that must be taken into account when testing for allergenic potential, is that allergic responses usually have a biphasic course. The induction period between initial contact with the causative agent and the development of skin sensitivity may be as short as two days for strong sensitizers such as poison ivy extract, or may require several years for a weak sensitizer such as chromate; for most of the chemical compounds with allergenic potential the induction period usually takes from 10 to 21 d. After this initial development of sensitivity to a certain allergenic chemical, the time between reexposure to this agent and the occurrence of clinical allergic symptoms is generally between 12 and 48 h; in animal testing, this period is called the challenge phase.

The general objectives are to determine whether there are indications from human experience of skin allergy or respiratory hypersensitivity following exposure to the agent and whether the agent has skin sensitization potential based on tests in animals. There are two methods currently described in EU Annex V and OECD guidelines for skin sensitization in animals: the guinea pig maximisation test (GPMT) and the Buehler test. The GPMT is an adjuvant-type test in which the allergic state (sensitization) is potentiated by the use of Freund's Complete Adjuvant (FCA). The Buehler test is a non-adjuvant method involving topical application for the induction phase rather than the intradermal injections used in the GPMT (Table 28; for reviews see references [158, 159]. Although they differ by route and frequency of treatment, they all utilize the guinea pig as test species. In general, for the induction phase the chemical is administered to the shaved skin intradermally, epicutaneously, or by both routes several times over a period of two to four weeks. Freund's complete adjuvant (FCA, a mixture of heat-killed *Mycobacterium tuberculosis*, paraffin oil, and mannide monooleate) is often included to increase the immunological response. During the challenge phase, a nonirritating concentration of the chemical is applied. The concentration of the test chemical and the application route (epi- or intradermal) are often different between the two phases. Sensitization is assessed by examining the skin reactions (edema, erythema) following the challenge phase and comparing them with any skin reactions observed immediately after the induction phase; the latter reactions are considered to result from direct irritating (toxic) properties of the test chemical. Hence, the difference between the symptoms observed after the induction and after the challenge phase is attributed to the allergenic effects of the chemical.

Table 28. Guinea pig sensitization tests

Test	Induction: route/number of applications	Challenge: route/number of applications
Draize	intradermal/10	intradermal/1
Open epicutaneous	epidermal open/20	epidermal open/1
Buehler	epidermal occlusive/3	epidermal occlusive/1
FCA*	intradermal in FCA*/3	epidermal open/1
Split adjuvants	epidermal occlusive/4 + FCA* intradermal/1	epidermal occlusive/1
Optimization	intradermal + FCA*/10	intradermal/1 epidermal occlusive/1
Maximization	intradermal + FCA*/1 epidermal occlusive/1	epidermal occlusive/1

* FCA = Freund's complete adjuvant.

The guinea pig maximization test is the most widely used and is considered to be very sensitive. The first part of the induction phase includes simultaneous injection of FCA alone, the test compound in saline, and the test compound in FCA into three different areas in close proximity to each other. The second part of the induction phase 7 d later employs epicutaneous application of the chemical on a filter paper, which is occluded and left in place for 48 h. The challenge phase is conducted epicutaneously for 24 h, two weeks after the induction phase. The maximization test is very sensitive and may produce false positive results. The original procedure (injection of the test compound) does not allow testing of final product formulations. Therefore, a modified procedure has been developed. In the first week, the FCA is injected four times and the test product formulation is administered epidermally, as in the second induction week.

Both the GPMT and the Buehler test have demonstrated the ability to detect chemicals with moderate to strong sensitization potential, as well as those with relatively weak sensitization potential. These guinea pig methods provide information on skin responses, which are evaluated for each animal after several applications of the substance, and on the percentage of animals sensitized.

The murine local lymph node assay (LLNA) is another accepted method for measuring skin sensitization potential. It has been validated internationally and has been shown to have clear animal welfare and scientific advantages compared with guinea pig tests. In June 2001, the OECD recommended that the LLNA should be adopted as a stand-alone test as an addition to the existing guinea pig test methods.

Respiratory hypersensitivity is a term that is used to describe asthma and other related respiratory conditions, irrespective of the mechanism by which they are caused. When directly considering human data in this document, the clinical diagnostic terms asthma, rhinitis, and alveolitis have been retained.

There are currently no internationally recognised test methods to predict the ability of chemicals to cause respiratory hypersensitivity. Potentially useful test methods based on allergic mechanisms are the subject of research and development. However, there are currently no test methods under development which are designed specifically to identify chemicals that cause respiratory hypersensitivity by nonimmunological mechanisms.

4.6. Phototoxicity and Photosensitization Testing

The biologically active spectrum of light can be divided into UV (220–400 nm) and visible light (400–760 nm). The UV spectrum is further divided into UVA (315–400 nm), UVB (280–315 nm), and UVC (220–280 nm); the last-named is absorbed in the stratosphere and does not reach the surface of the earth. The primary source of toxic effects on the skin is UVB, although UVA may also play a critical role in some reactions.

Xenobiotics localized within the skin may be activated by UVB and induce phototoxicity and/or photosensitization (photoallergy). Photoallergy is similar, both mechanistically and clinically, to allergic contact dermatitis, the only difference being that the chemical must react with light to become allergenic. Photoallergic reactions are not necessarily dose-dependent and show great variability between individuals. In analogy, phototoxicity may be compared with irritant dermatitis. Many phototoxic reactions may be caused by the formation of free radicals followed by lipid peroxidation and localized inflammation. In addition to phototoxicity and photoallergy, light-induced activation of chemicals may cause depigmentation, induction of an endogenous photosensitizer or of a disease characterized by photosensitization such as lupus erythematodes or pellagra. However, these reactions are comparatively rare. The tests to identify photoallergenic and phototoxic chemicals are performed in analogy to the tests for skin sensitization and irritation, respectively.

Photoallergenic potential is evaluated by repeated application of the test compound on the skin of guinea pigs and exposure of the treated area with UV light after every application; the UV treatment should cause a very slight erythema. Several days after this induction phase, the challenge phase is conducted by treatment with a low dose of the test compound together with UV light. Phototoxic reactions can usually by observed after the first exposure to the test compound together with UV light; in addition to guinea pigs, mice and rabbits are also utilized in tests for phototoxicity.

4.7. Reproductive and Developmental Toxicity Tests

The general objectives of reproductive and developmental toxicity testing are to establish whether exposure to the chemical may be associated with adverse effects on reproductive function or capacity, and whether administration of the substance to males and/or females prior to conception and during pregnancy and lactation causes adverse effects on reproductive function or capacity. Another focus of these studies are induction of nonheritable adverse effects in the progeny and whether the pregnant female is potentially more susceptible to general toxicity.

Reproductive and developmental toxicity is a very broad term including any adverse effect on any of the following aspects:

1. Male or female sexual structure and function (fertility)
2. Development of the new organism through the period of major organ formation, organogenesis (embryotoxicity and teratogenicity)
3. Development of the new organism during the peri- and postnatal periods

The field of reproductive toxicology has become increasingly important with the recognition that viral and bacterial infections and xenobiotic chemicals can produce

severe and irreversible defects in the offspring. The first reports on malformations due to rubella virus infections, ionizing radiation, hormones, dietary deficiencies, and chemicals appeared in the 1930s and 1940s, but the potential impact of reproductive toxicity on public health was only recognized more than two decades later. In 1960, a large increase in newborns with specific limb malformations, which are rarely seen otherwise, was recorded in Germany and in other parts of the world. One year later, the sedative/hypnotic drug thalidomide was recognized as the causative agent. The thalidomide epidemic resulted in 10 000 malformed children and subsided after the drug was withdrawn from the market at the end of 1961. One important consequence of the thalidomide disaster was the introduction of requirements for the testing of potential new drugs for reproductive toxicity. All test batteries required include detailed tests for reproductive toxicity to prevent a repetition of the thalidomide disaster.

The first specific reproductive toxicity test to be conducted is usually the two-generation study. which should be initiated after the rat 90-d subchronic repeated-exposure study, since the results obtained may provide information necessary for selecting dose levels for the two-generation study. Additionally, repeated-exposure studies that can provide information relevant to reproductive toxicity should be used in the design of the two-generation study. For example, the observation of neurological effects may indicate the need to evaluate developmental neurotoxicity.

The first developmental toxicity study is normally performed after completion of the two-generation study. The design of the developmental toxicity study should use all information derived from the repeated-exposure and two-generation studies, in particular dose–response relationships and information on maternal toxicity. The preferred species for the two-generation study is the rat; the necessity of a developmental toxicity study in the rabbit is dependent on the outcome of the first study.

4.7.1. *Fertility and General Reproductive Performance*

Segment I experiments are usually conducted in rats (20 animals of each sex per dose) with three doses of the test chemical, most often administered with diet. The treatment must not cause general systemic toxicity in the parental organism; therefore, in dose selection the dose levels are chosen according to observations in studies of subacute and subchronic toxicity, which are usually performed before testing for reproductive toxicity. Young adult male rats are treated for 60–80 d prior to mating to cover a whole period of spermatogenesis. Female rats are pretreated for 14 d to cover three estrous cycles. Treatment of both sexes is continued during the mating period and that of females throughout pregnancy. Half of the females are sacrificed just before term, and the numbers of resorbed and dead fetuses as well as structural abnormalities in the developed fetuses are assessed. In the United States, pregnancy is interrupted midterm in half of the females. Treatment of the remaining females is continued through parturition and lactation until weaning of the newborns, usually 21 d after birth. The young animals (F_1 generation) are reared without receiving the test compound until sexual maturity, when their fertility is assessed. During the rearing period, the development of the young animals is monitored with cage-side carefully clinical observations. If an adverse effect on fertility, pregnancy, or development of the offspring is observed, it is necessary to evaluate whether the effect is due to toxicity to the male or female reproductive system or both. This information can be obtained by separate mating of treated males with untreated females and vice versa.

Furthermore, evaluation of toxic effects on the male and female reproductive systems with specific test systems may be required. The effect of the test compound on male reproductive performance may be evaluated by monitoring mating behavior (e.g., frequency of copulation). Structural and functional impairment of the male reproductive organs is assessed by conducting gross pathology and histology of the testes and sperm analysis (viability, motility, and morphology). Histological examination of the ovaries plays an important role in assessment of toxic effects on the female reproductive system.

4.7.2. *Embryotoxicity and Teratogenicity*

Segment II studies assess adverse effects during the period of organogenesis. Xenobiotics interfering with the developing organism during this extremely sensitive period may cause severe and irreversible structural malformations. These studies are carried out in two species, usually rats (20 per dose) and rabbits (10 per dose); in most cases, two dose levels and an untreated control group are included. Pregnant animals are tested during the period of organogenesis: days 6 to 15 for rats and 6 to 18 for rabbits. The fetuses are delivered by cesarean section one day prior to the estimated time of delivery: day 21 for rats and day 31 for rabbits. The main reason for avoiding natural delivery is to prevent loss of deformed or dead fetuses by cannibalism, which happens in rodents and rabbits. The uterus of the maternal animal is excised, weighed, and examined for implantation sites and resorbed fetuses. The pups are weighed, and one-half of each litter is usually examined for skeletal defects and the remaining one-half for soft-tissue defects.

4.7.3. *Peri- and Postnatal Toxicity*

For segment III studies, treatment of pregnant rats with three dose levels (10–12 animals per dose) begins on day 16 of gestation and is carried on through delivery and lactation, until weaning of the offsprings, normally on day 21 postpartum. Treatment during parturition and lactation is also performed in segment I studies; however, segment III studies may offer additional information since higher doses can be used than in segment I. The peri- and postnatal segment evaluates effects on birth weight and survival as well as development of the offspring in the postnatal period. However, extrapolation of results of segment III studies from the rat to the human situation should be performed with care and consideration of the specific circumstances in each species. In contrast to the human situation, where in addition to the mother the social environment takes care of the newborns, young rats depend completely on the functional integrity of the maternal organism. Furthermore, the organism of newborn rats is significantly less mature by the time of delivery than that of newborn humans. Hence, treatments that affect the maternal organism simply by causing sedation or fatigue may significantly impair the development of newborn rats in the first 21 days of life. Such effects should not be automatically interpreted as relevant for postnatal toxicity in humans.

4.7.4. *Multigeneration Studies*

Multigeneration studies assess the cumulative effects of continuous application of the test chemical on reproduction and development during two or three generations. This application mode is relevant for long-term exposure to chemicals in the environment, such as pesticide residues in food or contamination of drinking water with agricultural chemicals or nonbiodegradable solvents.

The two-generation study is a general test which allows evaluation of the effects of the test substance on the complete reproductive cycle including libido, fertility, development of the conceptus, parturition, postnatal effects in both dams (lactation) and offspring, and the reproductive capacity of the offspring. The two-generation study is preferable to the one-generation study because the latter has some limitation regarding assessment of post-weaning development, maturation, and reproductive capacity of the offspring. Thus, some adverse effects such as oestrogenic- or antiandrogenic-mediated alterations in testicular development may not be detected. The two-generation study provides a more extensive evaluation of the effects on reproduction because the exposure regime covers the entire reproductive cycle, permitting an evaluation of the reproductive capabilities of offspring that have been exposed from conception to sexual maturity. The prenatal developmental toxicity study only provides a focused evaluation of the potential effects on prenatal development.

Three dose levels are usually given to groups of 25 female and 25 male rats shortly after weaning at days 30 to 40 of age. In the multigeneration study, these rats are referred to as the F_0 generation. The F_0 generation is treated throughout breeding, which occurs at about 140 d of age, and the female animals also during pregnancy and lactation. Hence, the offspring (F_1 generation) has been exposed to the test compound in utero, via the maternal milk, and thereafter in the diet. In many protocols, the F_1 generation is standardized to include certain numbers of animals, e.g., eight animals per litter. In analogy to the F_0 generation, the F_1 generation is bred at about 140 d of age to produce the F_2 generation. In some of the parents (F_0 and F_1 generations), gross necropsy and histopathology is conducted with greatest emphasis on the reproductive organs. In addition, necropsy and histopathology are carried out in all animals dying during the study.

The percentage of F_0 and F_1 females that become pregnant, the number of pregnancies carried to full term, the litter size, and number of resorptions, stillborns, and live births are recorded. Viability counts and pup weights are recorded at birth, and at days 4, 7, 14, 21 and 28 of age. With these data, the following parameters are calculated for assessment of the long-term reproductive toxicity of the test compound:

$$\text{Fertility index}\,(\%) = \frac{\text{Number of pregnancies}}{\text{Number of matings}} \times 100$$

$$\text{Gestation index}\,(\%) = \frac{\text{Number of litters}}{\text{Number of bred females}} \times 100$$

$$\text{Birth index}\,(\%) = \frac{\text{Number of pregnancies resulting in live off spring}}{\text{Number of pregnancies}} \times 100$$

$$\text{Viability index}\,(\%) = \frac{\text{Number of animals alive at day 4 after birth}}{\text{Number of new borns}} \times 100$$

$$\text{Lactation index}\,(\%) = \frac{\text{Number of animals alive at day 28 after birth}}{\text{Number of animals alive at day 4 after birth}} \times 100$$

4.7.5. *The Role of Maternal Toxicity in Teratogenesis*

If an agent with selective developmental toxicity is administered throughout the organogenesis period (days 6 to 15 in the rat), identifying the most sensitive target organs becomes difficult. In addition, teratogenic effects may be masked by embryolethality with repeated dosing during the organogenesis period. Developmental toxicity in the form of increased resorption and decreased fetal body weight is generally accepted to occur at maternally toxic dose levels. The role of maternal toxicity in causing congenital malformations, however, is not clear. Doses causing maternal toxicity, as indicated by reduced maternal body weight, clinical signs of toxicity, or death, commonly cause reduction in fetal body weight, increased resorption, and rarely, fetal deaths. Three patterns of association between maternal toxicity and malformations can be observed: (1) for some compounds, maternal toxicity is not associated with malformations; (2) for others, maternal toxicity is associated with a diverse pattern of malformations, often including cleft palate; and (3) the maternal toxicity of still others is associated with a characteristic pattern of malformations.

Compounds in the second category are the most difficult to classify in terms of teratogenic potential. Cleft palate is the principal malformation resulting from food and water deprivation during pregnancy in mice; however, cleft palate is also a malformation specifically induced in mice by a number of teratogens, most notably the glucocorticoids, without apparent maternal toxicity. Complete determinations of food and water consumption, maternal body weights, and impairment of the maternal organism are necessary to distinguish between cleft palate caused by the teratogenic effect of a chemical on the embryo and that resulting from systemic maternal toxicity, which secondarily affects embryonic development. The association of maternal toxicity with major malformations, such as exencephaly and open eyes, is not generally accepted, although most investigations agree that maternal toxicity can cause minor structural abnormalities such as variants in the ribs.

4.7.6. *In Vitro Tests for Developmental Toxicity*

Models to elucidate the mechanism of embryogenesis have been under development for several decades, and therefore developmental toxicology is a fields in which alternative methods to animal experimentation are available. However, because of the complicated, multistep nature of the development of a new life, none of the in vitro systems presently available can replace the animal tests. In vitro tests rather serve for screening purposes, i.e., to preclude the extensive traditional whole-animal test protocol for compounds with marked toxicity on reproduction and development. The existing alternative test systems fall into six groups: lower organisms, cell-culture systems, organ-culture systems, whole-embryo cultures, embryos, and others (Table 29). Since none of the in vitro methods is sufficiently validated for a set of compounds for which the effects on humans or animals are known and the field is much too extensive to be comprehensively reviewed here, the reader is referred to two comprehensive reviews of this field [160].

Table 29. In vitro test systems for developmental toxicity

Group	Test system/organisms	End points monitored
Lower organisms and small animals	sea urchins	growth
	drosophila	
	trout, medaka (fish species)	
	plania	
	brine shrimp	
	animal virus	
Cell culture	pregnant mouse and chick lens epithelial cell	protein synthesis
	avian neural crest	cell differentiation
	neuroblastoma	cell differentiation
Organ culture	frog limb	regeneration
	mouse embryo limb bud	morphological and biochemical differentiation, toxicity
	metanephric kidney organ culture from day 11 mouse embryos	morphological and biochemical differentiation
Whole embryo cultures	chick embryo	embryotoxicity, malformations
	frog embryo teratogenesis assay	lethality, no observed-effect-level, development stage, attained growth, motility, pigmentation,
		gross anatomical malformations
	rat embryo culture (postimplantation embryo)	viability, growth and macromolecular content, gross structural and histological abnormalities

4.8. Bioassays to Determine the Carcinogenicity of Chemicals in Rodents

Despite the many available short-term in vivo and in vitro tests to determine the genotoxic and carcinogenic potential of chemicals and the vast amount of literature on the subject, the lifelong carcinogenicity bioassay remains the main instrument for reliable evaluation of the carcinogenic properties of a xenobiotic. The principal guidelines for performing bioassays were established some 25 a ago by the U.S. National Cancer Institute and have essentially been adopted with slight alterations by all regulatory authorities (Table 30).

Table 30. Basic procedures of rodent carcinogenicity bioassays

Species	rat (Fischer 344, Sprague – Dawley, Wistar)
	mouse (B6C3F1, CD)
Age of animals at the beginning	4 to 6 weeks (shortly after weaning)
Number of animals	50 per sex per dose for carcinogenicity
	10 – 20 for additional studies during the course of experiment
Dose	at least three doses and vehicle control
	maximum tolerated dose
	intermediate dose
	nontoxic dose
Duration	24 months
Application	gavage, in feed, drinking water, inhalation (only if absolutely necessary)
Toxicologic pathology	all animals: gross necropsy
	weight of all important organs
	histopathology of all tissues (ca. 40) and all tumors and preneoplastic lesions by two independent pathologists

A number of factors may interfere with the analysis and interpretation of data from animal carcinogenicity studies. A variety of statistical techniques has been developed to adjust for confounding factors and to estimate confidence intervals and significance of results. Significance tests are used to assess neoplastic response in treated groups as compared to control groups or historical controls (cancer incidence in the identical strain and species observed in control groups for other cancer bioassays under identical housing conditions in the same facility). To estimate the absolute cancer risk posed by a specific chemical, background or spontaneous cancer incidences (induction of neoplasms not related to the administration of the test chemical) must be well defined. In general, high background incidences of cancer such as liver cancer observed in specific strains of mice requires larger number of animals in the treatment groups to detect increases in cancer incidence induced by the administration of the test chemical and to obtain statistically significant results. The demonstration of a dose–response curve for the cancer incidence in groups of animals treated with different doses of the carcinogen will increase the confidence in positive results of an animal cancer bioassay. The same holds for identical results observed with cancer as an endpoint in an independent study.

However, despite the importance of animal cancer bioassays for characterizing chemical carcinogens, this approach has been criticized recently (see also Section Interpretation of Data from Chronic Animal Bioassays). Due to the influence of rodent carcinogenicity assay on the development of new chemicals and pharmaceutical drugs, the pros and cons of this type of assay are discussed in depth in the following.

Practically all chemicals identified as human carcinogens produce tumors in the rodent bioassay. Hence, the test has a very good predictive value, and every chemical exerting carcinogenicity in rodents should be handled as a potential human carcinogen. Considering the many new chemicals developed each year, two major disadvantages of the life-long assay are its high cost and long duration. A two-year gavage study in only one species amounts to approximately € 10^6 and takes 3–4 years or longer for complete evaluation. For optimized evaluation of carcinogenic properties, it is important to use animal species that are closest to humans with regard to biotransformation and toxicokinetics of the test compounds. However, for practical and financial reasons, only rodents can be used. Long-term carcinogenic bioassays in dogs or primates, for example, require seven to ten years for completion and are much more costly.

The application of the maximum tolerated dose (MTD) in rodent bioassays has been the subject of much controversy [161-167], but the experimental design limitations of in vivo studies make the application of high doses necessary. For example, if a specific dose of a chemical causes a 0.5% increase in human cancer incidence, this would result in several hundred thousands of additional cancer cases in a country such as Germany each year and would thus definitely pose an unacceptable risk. However, the identification of this 0.5% increase in cancer incidence with statistical confidence in the rodent bioassay would require a minimum of 1000 animals, provided the incidence of spontaneous tumors is zero. Therefore, there seems to be general agreement that the use of the MTD, although not an optimum solution, is necessary for risk assessment. According to the U.S. National Cancer Institute, the MTD is defined as “the highest dose that can be predicted not to alter the animals' normal longevity from effects other than carcinogenicity”. In practical terms “MTD is the dose which, in the subchronic three-months toxicity study causes not more than a 10% weight decrement as compared to the control groups and does not produce mortality, clinical signs of toxicity, or pathological lesions other than those which may be related to a neoplastic response that would be predicted to shorten an animal's life span”. As stated above, the MTD is determined in the preliminary three-month studies on subchronic toxicity, where it fulfills the above requirements. Ideally, this is exactly what should also happen in the 24-month carcinogenicity study. However, due to cumulation of toxic effects and/or alterations in toxicokinetics of the xenobiotics during the study, for example, induction of toxification or detoxification pathways by application of the xenobiotic in high doses, the MTD dose group often shows reduced survival rates in the life-long bioassay. This may invalidate the study, that is, make it inadequate for evaluation of the carcinogenic potential. Indeed, this is not a rare event in carcinogenicity studies. The opposite effect may also occur: due to toxicokinetic differences between the three- and 24-month studies, the MTD chosen may turn out too low in the long-term bioassay. In spite of all these problems and because of the absence of a satisfactory alternative solution, the use of the MTD is currently the only method to compensate for the fact that in relation to the human population exposed to potential carcinogens, the numbers of rodents used in the carcinogenicity bioassay are extremely low. The legitimate argument against the MTD is that any chemical given at a sufficiently high dose level will induce adverse effects. This understanding, which is beyond dispute in toxicology, has been tentatively generalized by several scientists in recent years by the notion that carcinogenic effects obtained at the MTD may exclusively result from target-organ toxicity, and the increased cell proliferation may contribute to tumor formation by increasing the rate of spontaneous mutations, since DNA replication does not take place with 100% fidelity. Furthermore, during increased cell turnover, the time available to repair DNA damage is reduced, so that an increased number of damaged DNA sites may be converted to heritable mutations. Although this may be the mechanism underlying the carcinogenic effects of some nongenotoxic chemicals, it can not be generalized to every tumor observed at the MTD. Toxicity and cell proliferation do not necessarily result in tumor formation. Table 31 summarizes the important differences between rodent bioassays and human exposure to carcinogens.

Table 31. Some important differences between carcinogenicity tests in rodents and human exposure to potential carcinogens

Rodent carcinogenicity test	Human exposure
High doses	(usually) low doses
Continuous exposure	(often) infrequent or not regular exposure
Single compound, no interactions	simultaneous exposure to several carcinogenic chemicals, interactions probable
Homogeneous population	heterogeneous population

In addition to these problems, which are inherent in the bioassay procedure, the evaluation of the toxicological pathology has repeatedly become an issue of debate, since differences in evaluations between pathologists are frequent. This does not necessarily indicate incompetence of one of the pathologists. The different evaluations may be the result of difference in terminology. Also, sometimes evaluations are conducted years apart, and in the interim period understanding of the pathogenesis of lesions may have changed. Thus, even the same pathologist may not come to the same conclusion when reevaluating tissue slices several years after the first examination.

Due to the uncertainties of rodent bioassays and the extremely high costs and personnel requirements, a multitude of short-term tests has been developed in recent years. These tests aim to predict the carcinogenic potential of chemicals. Most of these in vitro tests are based on damage to the genetic material (genotoxicity) by the chemical or its metabolites. Genotoxicity is without doubt the field in toxicology with the best established and validated in vivo and in vitro short-term tests.

4.9. *In Vitro* and *In Vivo* Short-term Tests for Genotoxicity

Genetic toxicology a comparatively new field of research that has rapidly grown since the 1960s, deals with mutagenicity and genotoxicity.

Mutagenicity is the induction of permanent transmissible changes in the genetic material of cells or organisms. Changes may involve a single gene or gene segment, a block of genes, or whole chromosomes. Effects on whole chromosomes may be structural and/or numerical.

Genotoxicity is a broader term and refers to potentially harmful effects on genetic material which may not be associated with mutagenicity. Thus, tests for genotoxicity include systems which give an indication of damage to DNA (no direct evidence of mutation). End points determined here are unscheduled DNA synthesis (UDS), sister-chromatid exchange (SCE), DNA strand breaks, formation of DNA adducts and mitotic recombination.

Evidence has increasingly accumulated that many carcinogens are also mutagenic, and a large number of short-term in vitro and in vivo tests were developed as predictive tools. Most of these tests are well validated and aim to assess genotoxic properties of chemicals. Today, the majority of potential carcinogens are first identified as mutagens or chromosome-damaging agents in short-term tests and subsequently as carcinogens in the rodent carcinogenicity bioassay. The numerous in vivo and in vitro assays can be categorized into two major groups:

1. Short-term tests detecting gene mutations
2. Short-term tests detecting structural and/or numerical chromosomal aberrations

A number of these in vitro test procedures have gained regulatory acceptance for toxicology testing (Table 32).

In vitro tests to detect gene mutations can be categorized into two groups: microbial and mammalian cell assays. An important step in the history of modern genetic toxicology was the development of genetically precisely defined strains of bacteria carrying mutations in particular genes coding for enzymes involved in the biosynthesis of amino acids. Among the numerous tests, the most widely used and best validated is the assay in *Salmonella typhimurium* developed by AMES et al.

4.9.1. *Microbial Tests for Mutagenicity*

4.9.1.1. *The Ames Test for Bacterial Mutagenicity*

The most common method to detect mutations in microorganisms is selecting for reversions in strains that have a specific nutritional (i.e., amino acid) requirement differing from wild-type members of the species; the tester strains are “auxotroph” for this particular nutrient. The *Salmonella typhimurium* mutant strains developed by AMES can not synthesize histidine, because each strain carries one of a number of mutations in in the operon (group of genes) coding for histidine biosynthesis [168, 169]. The result of this mutation is that the tester strains can not grow and form colonies in histidine-free medium. The mutation may revert to the wild-type sequence or a functionally equal sequence either spontaneously (a rare event) or by exposure of the tester strains to genotoxic compounds. The revertant colonies are, like the wild-type bacteria, capable of synthesizing histidine and form colonies in histidine-free medium. For the common tester strains, the DNA sequence at the site of the original mutation in the relevant histidine gene has been determined. According to the type of mutation leading to the inability to synthesize histidine, the strains can be categorized into two groups: base-substitution and the frameshift strains. The difference between these two categories can be illustrated with the following sentence, in which each letter represents a DNA base, each word a triplet coding for an amino acid, and the whole sentence a gene coding for a protein (i.e. enzyme of histidine biosynthesis). The correct sentence represents the gene in the wild-type strain.

THE NUN SAW OUR CAT EAT THE RAT	original sentence (wild-type)
Base-pair substitution:	
THE **S**UN SAW OUR CAT EAT THE RAT	missense mutation coding for a wrong amino acid
THE N**S**N SAW OUR CAT EAT THE RAT	nonsense mutation resulting in interruption of gene transcription
Frameshift mutation:	
THE NUN SA**S** WOU RCA TEA TTH ERA T + 1-frameshift mutation	

This example illustrates that a base substitution can be reverted by another base substitution and in analogy a frameshift mutation can be reverted by another frameshift mutation. Hence, the Ames test not only provides information on the genotoxic potential of the test compound but also on the nature of the DNA damage.

Genetic Makeup of the Salmonella typhimurium Strains Used in the Ames Test. *Histidine mutations of the tester strains*. The base-pair substitution strains can be categorized into two families.

1. The *Salmonella typhimurium* strains TA100 and TA1535 carry the sequence CCC (for leucine) instead of the wild-type sequence CTC (for proline). These missense mutations may be efficiently reverted by mutagens with alkylating properties.
2. The second group of base-pair substitution strains carry a nonsense mutation (TAA instead of CAA). These strains (TA2638, TA100) may detect mutations induced by radicals or oxidizing agents such as hydrogen peroxide and reactive oxygen matabolites.

The commonly used frameshift strains TA98 and TA1538 carry a +1 frameshift mutation near a GCGCGCGC sequence. This strain may be used to detect frameshift mutagens such as polycyclic aromatic hydroxycarbons, certain aromatic amines, and certain aromatic nitro compounds.

In addition to the mutation in one of the genes of histidine biosynthesis, the Ames strains carry additional genetic alterations that increase their sensitivity to detect mutagens (an overview of the genetic make-up of the *Salmonella typhimurium* tester strains is provided in Table 33).

Table 33. Genetic makeup of commonly used Salmonella typhimurium tester strains

Strain	Histidine mutation		Additional genetic alteration
	Location	Route	
TA100	his G46	CCC instead of CTC	*uvrB*
		base substitution results in proline instead of leucine	*rfa*
			*pkM*101
TA1535	his G46	CCC instead of CTC	*uvrB*
		base substitution results in proline instead of leucine	*rfa*
TA2638	his G428	ATT nonsense mutation	*rfa*
	his G8476	results in interruption of transcription	*pkM*101
TA102	his G428	multiple copies of plasmid pAQ1 carry the revertible nonsense	*rfa*
		mutation ATT	*pkM*101
TA98	his D3052	-1-frameshift mutation with a GCGCGCGC sequence	*uvrB*
			rfa
			*pkM*101
TA1538	his D3052	-1-frameshift mutation with a GCGCGCGC sequence	*uvrB*
			rfa

rfa Mutations. The *rfa* mutation results in a defective lipopolysaccharide membrane and thus increases the permeability of the cell wall to bulky hydrophobic chemicals. In addition, strains with defective cell walls are not pathogenic to experimental animals and humans.

uvrB Deletion. Wild-type bacteria possess several effective DNA repair systems, that operate practically error free and can repair DNA damage without allowing mutations to occur. To overcome the problem of DNA repair and thus the decreased sensitivity of the test system, AMES constructed a series of strains with a deletion of the *uvrB* gene, which codes for a subunit of an important enzyme (the cor-endonuclease-I) of the error-free excision repair system. This change increases the sensitivity of the tester strains to mutagens by several orders of magnitude.

The plasmid pkm101. Wild-type *Salmonella typhimurium* strains do not process an “error-prone” DNA repair which is found for example in *Escherichia coli* and some other members of the Enterobacteriaceae. In contrast to the above-mentioned error-free excision repair pathway, the error-prone system operates with low fidelity and introduces new mutations into the genome while repairing a damaged DNA site. To overcome this deficiency and to increase sensitivity to mutagens, the gene for the error-prone repair system has been introduced into some of the *Salmonella typhimurium* tester strains with the plasmid pkm101. This plasmid also carries the genetic information for ampicillin resistance, an important property for monitoring the physiological integrity of the tester strains in the course of the experiments.

The plasmid pAQ1. The *Salmonella typhimurium* strain TA 102 carries the revertible histidine mutation on multiple copies (approximately 30) of the plasmid pAQ 1 and not on the chromosome. Reversion of one of these copies returns the bacteria's capability to synthesize histidine. This increase in sensitivity is partly offset

because strain TA 102 has an intact excision repair system (it does not have the *uvrB* deletion). This strain has been constructed because DNA interstrand cross-linking agents such as the quinone mitomycin C or the combination of psoralens und UV light require an intact excision repair system to generate mutations. DNA interstrand cross-links must first be removed from one strand along with a small number of adjacent bases by excision repair. The gap left behind is repaired, and the remaining broken cross-link attached to the other strand is a premutagenic lesion that may give rise to a mutation by error-prone repair.

The Problem of Bioactivation in the Ames Test. The majority of the mutagenic xenobiotics require bioactivation (toxification) to reactive electrophiles to induce DNA damage. The main disadvantage of bacterial mutagenicity assays is that the tester strains do not express many of the enzymes that bioactivate xenobiotics in mammals. For example, cytochrome P450 activity is not detectable with most substrates in *Salmonella typhimurium*. Therefore, there is a need to simulate the biotransformation occurring in the intact animal by supplementing the test system with the enzymes of bioactivation and the necessary cofactors. For this purpose, numerous exogenous metabolic systems have been used in the last decades. They can be grouped into cell-free and cell-based systems, and among the cell-free systems the 9000 *g* supernatant (called S-9 fraction, the S-9-fraction with the cofactors necessary for enzyme activity is called S-9 mix) from rat liver is the most widely used and best validated.

Preparation of S-9 Fraction and S-9 Mix. S-9 fraction is usually prepared from the liver of male adult rats. Preparations from uninduced animals may contain only low activities of important enzymes of bioactivation such as cytochrome P450 1A1. Since these deficiencies could limit the use of the S-9 fraction as exogenous activating systems in bacterial assays, the rats are usually pretreated with enzyme inducers. Among them Aroclor 1254, a mixture of polychlorinated biphenyls, is the most widely used. Pretreatment of the rats with Aroclor 1254 results in induction of a broad range of cytochrome P450 enzymes. For specific purposes, more selective inducers of cytochrome P450 enzymes such as phenobarbital (cytochrome P450 2A1, P450 2B1) and 3-methylcholanthrene (cytochrome P450 1A1) may be also used.

The livers are removed from the animals after sacrifice at specific time intervals after application of the inducer, minced, homogenized, and centrifuged at 9000 *g* for 15 min. The monooxygenases contained in this S-9 supernatant require NADPH as cofactor, which is normally generated by glucose-6-phosphate dehydrogenase from glucose-6-phosphate by reducing $NADP^+$. Therefore, the S-9-fraction is also supplemented with these two cofactors and with magnesium and potassium salts to yield the final activating system, the S-9 mix. This standard S-9 mix is capable of performing phase-I biotransformation reactions (e.g. oxidations, reductions) but is deficient in most phase-II systems (conjugation reactions). The latter are often involved in detoxification reactions, while phase-I enzymes usually result in toxification of xenobiotics to more electrophilic metabolites. Hence, the S-9-mix may efficiently simulate bioactivation of xenobiotics in the liver, but not detoxification. This may be regarded as an advantage, since it usually increases the sensitivity of the system. On the other hand, the discrepancy between phase-I and phase-II enzymatic activities may be a source of false positive results because the genotoxicity observed in vitro may not reflect the in vivo situation, and detoxification may predominate in the intact animal. The deficiency in conjugation reactions may be partly overcome by adding appropiate cofactors for phase-II conjugation reactions, such asglutathione. The S-9 fraction from other organs may also be prepared and used for the bioactivation of organ specific carcinogens, for example, S-9-fraction of the renal cortex for compounds inducing renal cell tumors. Alternatively, cell-based systems may be used to bioactivate xenobiotics in bacterial mutagenicity assays. Freshly isolated hepatocytes or hepatocytes in primary culture retain the activity of the phase-I and phase-II enzymes of the intact liver and do not require the addition of cofactors for enzyme activity. However, besides greater technical difficulty in obtaining hepatocytes of good quality compared with S-9 fraction, additional problems arise when using intact cells because the electrophiles formed may have a very short half-life and may be trapped and react with macromolecules before diffusing out of the hepatocytes, resulting in false negative results.

An recent elegant approach to overcoming the deficiencies of the bacteria in biotransformation reactions is to clone genes of mammalian biotransformation enzymes into plasmids and to introduce these into tester strains. Although this approach has not been widely used so far, it seems to be a promising method for the future. For example, introducing the gene for *N,O*-acetyl transferase, an enzyme important in the bioactivation of aromatic amines, into *Salmonella typhimurium* TA 98 and TA 100 resulted in an approximately 100-fold increase in the corresponding enzymatic activity in the newly engineered strain. In contrast to the original strains, the *N,O*-acetyl transferase-proficient strains permitted efficient detection of the mutagenic activity of several nitroarenes and aromatic amines. A similar increase in the mutagenicity of bromo- and chloroalkanes was abtained with tester strains expressing a specific human glutathione *S*-transferase isoenzyme [170, 171]. Specific potentials and limitations of these tests follow:

•Potentials

- High reliability when testing known carcinogens and noncarcinogens
- Extensive data base available
- High sensitivity
- Information about the mechanism of mutations may be obtained by comparing results in different strains
- Rapid and inexpensive
- May be used as a bioassay to detect mutagenic components in complex mixtures

•Limitations

- Some important carcinogens are not active due to specific mechanisms of action (metals, particles, asbestos)
- Data are only qualitative
- Sample must be sterile
- Problems in testing bactericidal chemicals

Experimental Procedure for the Ames Test. Presently three different protocols are widely used for the Ames test: the plate-incorporation assay, the preincubation assay and the fluctuation test.

Plate Incorporation Assay. The basic procedure of the plate incorporation assay is illustrated in Figure 62. Briefly, 2.0 mL aliquots of soft agar overlay medium (Top Agar, 0.6% agar and 0.5% sodium chloride in distilled water) containing a trace of histidine and excess biotin and maintained in the liquid state at 45 °C, 100 µL of the tester strain, 20–100 µL of the test compound and, when necessary, 500 mL S9-mix (or another bioactivation system) are added. After mixing, the solution is poured onto dried Vogel–Bonner minimal medium plates. The plates carrying untreated, solvent, and positive (UV light or established mutagen) controls are incubated for 2 d at 37°C. At least ten concentrations of the test compound are usually tested with two plates per concentration.

Figure 62. Basic procedure for the Ames test/plate incorporation assay

50 to 200 plates are usually prepared and evaluated per test. At least ten concentrations of the test compound are examined with two plates per concentration level

Preincubation Assay. Some mutagens, particularly those metabolized to short-lived reactive electrophiles, may not be detected in the standard plate incorporation assay due to reaction of the electrophile with constituents of the medium. This type of xenobiotic may be detected more efficiently by using the preincubation assay protocol, in which the bacteria are preincubated with the test compound and S-9 mix in suspension for 30–120 min in the absence of top agar. After the end of this preincubation period, 2.0 mL of soft agar is added to each tube and the reaction mixture is poured into Vogel–Bonner plates, which are incubated as described above.

Fluctuation Test. In the fluctuation test, the number of mutants in a series of small independent replicate cultures is detected. Overnight bacterial cultures are incubated with the test compound and the appropriate metabolizing system (when necessary) in the presence of a trace of histidine. As in the other protocols, this trace of histidine allows a few replication cycles, which are necessary for expression of the mutations following the initial DNA damage. The above mixture is then divided into a large number (usually 50–100) of test tubes or microtiter plates. When the histidine trace is consumed, only revertant cells can grow. Test tubes or wells of the microtiter plates containing revertants become turbid, and the media turn acidic as a result of acid release during growth. This pH drop to 5.2–6.8 can be demonstrated by the color change of a pH indicator such as bromoethyl blue.

Scoring for Colonies in the Plate Incorporation and Preincubation Assay The limited growth of nonrevertant colonies due to the trace of histidine added to enable mutational expression of DNA damage results in a slight background lawn of growth. Therefore, before scoring the plates for revertant colonies, the background lawn should be examined either macroscopically or under the low magnification of a light microscope. At toxic concentrations of the test chemical, the plates appear clear. Also, at toxic concentrations of the test chemical, tiny colonies (minicolonies) may be formed. This happens when, at bactericidal concentrations of the test chemical, very few bacteria survive. The histidine trace usually added to the system may then be sufficient for formation of these minicolonies (pseudorevertants). Revertant colonies resulting from gene mutations are clearly larger and can be counted either by hand or with an automatic colony counter.

Evaluation of Results. A typical mutagenic dose–response curve is illustrated in Figure 63. From the linear part of the dose–response curve, the mutagenic potency of the test compound can be calculated and is usually expressed in number of revertants per nanomole of test compound. At higher, toxic concentrations of the test chemical, the curve may flatten. At concentrations which are very toxic to the bacteria, the number of revertant colonies may start to decline after reaching a maximum. The significance of the results is analyzed with usual statistical methods.

Figure 63. Typical dose – response curve in the Ames test

A) At nontoxic mutagen concentrations the number of revertants increases in a dose-dependent manner; B) Higher, toxic concentrations inhibit growth, which is reflected in flattening of the curve followed by decreasing numbers of obtained revertants

Role of the Ames Test in Evaluating Carcinogenic Properties.. The Ames test is a system to detect mutagenicity which has gained great practical importance as a short-term predictive test for potential carcinogenicity of a xenobiotic. Hence, the Ames test may predict the carcinogenic properties of genotoxic carcinogens, but not of nongenotoxic carcinogens. The very high correlation between mutagenicity and carcinogenicity found in previous reports (values of 90–95% were repeatedly estimated) are certainly not correct. One reason for this overestimation may be that in previous decades mainly structurally alerting chemicals (xenobiotics carrying functional groups present in other carcinogens and known or suspected to be metabolized to electrophiles) were tested for long-term rodent carcinogenicity, and most of these structurally alerting carcinogens are mutagenic. In contrast, more recently, more important environmental pollutants and occupational hazardous chemicals have increasingly been tested for carcinogenicity, independent on their chemical structure. As a result, an increasing number of carcinogenic compounds that do not react directly with DNA to cause mutations have been found. These xenobiotics are thought to act via additional and (unfortunately) only partly defined so,called epigenetic mechanisms (i.e., not involving genetic changes). Nongenotoxic carcinogens cannot be detected in the Ames test. In contrast to the genotoxic carcinogens, which are usually active in two species and/or at multiple sites, nongenotoxic carcinogens are often active in one species and at a single site, for example, branched chain hydrocarbons in the male rat kidney or peroxisome proliferators in the mouse liver. This is confirmed by comparing the carcinogenicity results with the bacterial mutagenicity. While more than 70% of the two-species/multiple-site carcinogens are positive in the Ames test, only 40% of the one-species/single-site carcinogens exert bacterial mutagenicity. Therefore, a reasonable evaluation of the results obtained in bacterial mutagenicity systems can only be conducted by taking into consideration additional information on the chemistry, toxicokinetics, biotransformation, and biological effects of the test compounds.

Presently, the Ames test is an important part of a screening battery for possible carcinogenic properties in the course of the development of new pharmaceutical drugs and chemicals. Depending upon the intended use of the chemical, the development may be interrupted if a compound is clearly positive in the Ames test and in an additional short-term test, often the in vivo micronucleus test (see Section *In Vivo* Cytogenetic Assays). With this “decision-point approach”, the number of unnecessary life-long bioassays in rodents is significantly reduced and large amounts of money and time may be saved.

4.9.1.2. *Mutagenicity Tests in Escherichia coli*

The *E. coli* tester strain WP2 and additional tester strains subsequently developed originate from the wild-type *E. coli* B strain; all tester strains are tryptophan(trp)-auxotrophic. For example, the *E. coli* WP2 trp E group has a terminating mutation at an AT base pair of the trp E gene which codes for anthranilate synthetase, an enzyme of the tryptophan biosynthetic pathway. Hence, the *E. coli* mutagenicity assays, like the Ames test, detect reversion of the deficiency to synthetize tryptophan. The *E. coli* tester strains have umuDC$^+$ genes coding for the error-prone repair system, and their membrane structure permit the passage of many large molecules. The experimental procedures and the inherent advantages and limitations are practically identical to those of the *Salmonella typhimurium* test. However, the *E. coli* test systems are less well validated than the Ames test, and this renders the selection of appropiate strains for the investigation of the mutagenicity of a specific xenobiotic and the interpretation of the obtained results more difficult.

4.9.1.3. *Fungal Mutagenicity Tests*

The most widely used species is *Saccharomyces cerevisiae*; the test detects reversion of the isoleucine auxotrophy induced by exposure to mutagens, in analogy to the Ames test.

4.9.2. *Eukaryotic Tests for Mutagenicity*

Although prokaryotic systems are fast, inexpensive and versatile, there is a requirement for mammalian test systems due to the important differences between prokaryotic and eukaryotic organisms in structure and function of the genome and in biotransformation and transport of xenobiotics. The eukaryotic systems for detecting mutations include tests in the fruit fly *Drosophila melanogaster*, in many different types of cultured mammalian cells, and in the intact animal in vivo.

4.9.2.1. *Mutation Tests in Drosophila melanogaster*

The fruit fly *Drosophila melanogaster* has a short generation time of 10 d and a similar cellular and chromosomal structure and function to mammalian cells. In addition, the genome of the fly is well characterized, and *Drosophila* species can perform many of the phase-I and phase-II reactions occuring in mammals. The *Drosophila* sex-linked recessive lethal test was a popular screening system in the 1970s and was used to screen many hundreds of compounds. However, since then the popularity of the test has waned drastically because of its poor performance in international collaborative trials that investigated the utility of mutagenicity assays as predictive tools. Another *Drosophila* test, devised in the 1980s, the somatic mutation and recombination test (SMART) seems promising but has not been sufficiently validated. Since both tests are not widely used for screening, the experimental procedures are not be described here (the interested reader may find them in reference [156]). Some potentials and limitations of the mutation tests in *Drosophila melanogaster* follow:

•Potentials

- Large number of test organisms can be raised
- Metabolic activation endogenous
- Genotoxic effects evaluated in germ cells
- Large data base on mutagens

•Limitations

- Some known carcinogens such as polycyclic hydrocarbons respond poorly
- Problems with toxic compounds (insecticides)

4.9.2.2. *In Vitro Mutagenicity Tests in Mammalian Cells*

Many short-time mutagenicity tests in mammalian cell lines have been developed. These systems have the advantage of determining genotoxic effects in relevant cell types and may permit the study of mechanisms of carcinogenicity. The potentials and limitations of these in vitro tests follow.

•Potentials

- Full range of mutational responses may be observed
- Low costs when compared to in vivo assays
- Respond to particulates and other types of compound not detected in the Ames test
- More relevant end point for mammals

•Limitations

- Most cell lines used are transformed cells and do not represent “normal” cells
- Only specific loci from the entire genome are monitored
- Most cell lines used are deficient in biotransformation enzymes

In contrast to popular bacterial assays that detect reversion mutations, the commonly used mammalian mutagenicity assays are based on the detection of forward mutations. A large number of cells is treated with the test compound. After a certain period of time, the cells are exposed to a toxic agent that is lethal to all cells not carrying mutations (i.e., only mutated cells can survive). Cultured mammalian cells are normally diploid and have two copies of each gene. Hence, recessive mutations may be missed if a normal copy is present on the homologous chromosome because the probability that a mutagenic compound alters genes is very low. Therefore, mutations are assessed in genes on the X chromosome in male cells, where only one copy of the gene is present. Alternatively, heterozygous cells are used, in which one copy of the gene is already inactivated.

Mammalian cells have genes that allow the cell to salvage nucleotides from the surrounding medium. These genes, although not essential for cell survival, save cellular energy, since the cell need not synthesize these molecules from simple precursors by energy-consuming pathways. If the medium is supplied with altered

nucleotides, the normal (not mutated) cell will incorporate them into the DNA, and this will result in cell death. However, if this salvage property is lost due to mutation, the mutated cells are not able to incorporate the toxic nucleotides from the surrounding medium and will survive and form colonies which can be detected as a parameter of genotoxicity. Although a gene may be inactivated by a mutation, the mRNA and the corresponding enzyme produced prior to the mutational event may be present for some time after exposure to the mutagenic test compound. Therefore, the cells have to be left for some time before challenging with the toxic nucleotide, this period is called expression time.

Basically, two genes of the salvage pathway are utilized in mutagenicity assays: the hypoxanthine–guanine phosphoribosyltransferase (HGPRT) gene and the thymidine kinase (TK) gene. The HGPRT gene is located on the X chromosome in humans and in the Chinese hamster, from which many useful cell lines have been developed. The genetic changes detected in the HGPRT gene as the target site are mainly point mutations because chromosomal deletions usually extend to flanking regions of the target gene, which may contain essential genes. Since only one copy of these essential genes exists in male cells, this results in cell death so that the cells in which the HGPRT gene is inactivated by deletion are usually lost for the test. This is not the case with the TK gene, because it is autosomal and heterozygous cells (TK^+/TK^-) are used in the assay. Here, both point mutations and changes at the chromosomal level can be detected. The HGPRT gene is the target gene in the Chinese hamster CHO and V 79 cell lines, while mouse lymphoma L 5178 Y $TK^+/^-$ cells detect mutations at the TK locus. The mechanistic background of these tests is shown in Figure 64.

Figure 64. Assessment of mutagenicity in mammalian cells

A) The V 79/HGPRT (hypoxanthine – guanine phosphoribosyltransferase) assay; B) The L 5178 Y $TK^+/^-$ (thymidine kinase) mouse lymphoma assay

Mutant cells do not form the lethal nucleotides and survive in the presence of 6-thioguanine or trifluorothymidine.

The use of Chinese hamster cell lines for mutagenicity screening is limited due to low sensitivity. Chinese hamster cell lines grow on monolayers and, owing to metabolic cooperation, only a relatively small cell population can be used. In contrast, L5178Y $TK^-/^-$ cells grow in suspension, and the system is not impaired by the problems of metabolic cooperation, because intercellular bridges do not occur. As described above, a wide variety of genetic events including gene mutations, recombinations and mitotic nondisjunction can result in the formation of the $TK^+/^-$ genotype from the heterozygote $TK^+/^-$. Two protocols have been devised for mutation assays with mouse lymphoma L5178Y cells:the plate test in soft agar and the fluctuation test in suspension. For dose-finding, a preliminary cytotoxicity assay is usually conducted when testing new compounds. In this assay, the cloning efficiency (for the plate test) or the relative suspension growth (for the fluctuation test) is determined. The highest test concentration for the mutation assay is usually the concentration that reduces cloning efficiency or suspension growth to approximately 10–20% of the control values. In addition, a moderate concentration causing survival reduction to 20–70% and a low concentration (> 70% survival) are also used. After treatment with the test compound (3–7 h; in the presence or absence of an exogenous metabolic system, e.g., S-9 mix) the cells are incubated for 2 d for mutation expression before exposure to trifluorothymidine for 10–12 d. In the presence of trifluorothymidine, only mutant cells can survive. Thus, the relative growth of the cells at the end of the experiment can be used as a parameter for mutagenicity.

4.9.3. *In Vivo Mammalian Mutation Tests*

In contrast to the well-established and widely used micronucleus tests in rodents (see Section *In Vivo* Cytogenetic Assays), the existing in vivo tests to detect gene mutations are not used for routine genetic toxicology testing; therefore, only brief descriptions are given here (for exact experimental procedure, see [156]).

4.9.3.1. *Mouse Somatic Spot Test*

The mouse somatic spot test detects the inactivation of genes at a set of heterozygous loci controlling hair pigmentation. Inactivation can be induced by a wide spectrum of genetic alterations ranging from gene mutations to major chromosomal changes.

4.9.3.2. *Mouse Specific Locus Test*

The mouse specific locus test consists of treating parental mice homozygote for a marker gene controlling coat pigmentation, intensity, and pattern or size of the external ear. Treated mice are mated with a tester stock that is homozygous recessive at the marker loci. The resulting F_1 generation is normally heterozygous at the marker genes and therefore expresses the wild-type phenotype. In the case of mutations at any of these genes, the F_1 offspring express the recessive phenotype. The mouse specific locus test has a comparatively low sensitivity, thus requiring that many thousands of newborns be scored. However, it remains an important method for investigating heritable mutations.

4.9.3.3. *Dominant Lethal Test*

The dominant lethal test assesses embryonic death resulting from genetic changes in parental germ cells. The procedure is based on observing the viability of uterine implantations. Implantations that die at an early stage form a deciduoma or mole. The genetic event resulting in early death is predominantly chromosomal damage in the parental germ cells resulting in a dominant lethal mutation. Although the assay was popular in the 1960s and 1970s as a screen for germ cell damage, it is not widely used at present because it is considered relatively insensitive.

4.9.4. *Test Systems Providing Indirect Evidence for DNA Damage*

4.9.4.1. *Unscheduled DNA Synthesis (UDS) Assays*

Two major DNA repair mechanisms have been identified in mammalian cells. The first mechanism involves direct reversal of DNA damage, such as cleavage of pyrimidine dimers that have been induced by UV light or removal of potentially mutagenic methyl groups from the O^6 position of guanine by O^6-methylguanine-DNA methyltransferases. The second mechanism recognizes damaged DNA bases, removes them after nicking the DNA backbone, fills the gap formed with the correct bases using the opposite strand as a template, and finally seals the second strand break.

The most widely used method to study DNA repair is the “unscheduled” DNA synthesis assay. The principle of the UDS assay consists in detection of the incorporation of radioactive DNA bases or chemical analogues of nucleotides such as bromodeoxyuridine into DNA in the course of excision repair after damaged bases have been removed. This unscheduled DNA synthesis induced by DNA damage must be distinguished from the semiconservative DNA synthesis during DNA replication. DNA replication can occur in the same cells that undergo repair or, alternatively, in other cells of the test population and usually contributes to an incorporation of radiolabeled base or nucleotide analogue in concentrations several orders of magnitude higher than repair. Three approaches are currently available to overcome this problem and to detect selectively DNA repair-dependent incorporation.

1. Use of quiescent cell populations, that do not replicate
2. Suppression of DNA replication by incubation in serum-reduced and arginine-depleted medium and pretreatment with the ribonucleotide reductase inhibitor hydroxyurea
3. Evaluation of radioactivity by autoradiography of single cells, which allows the distinction between heavily labeled replicating cells and lightly labeled DNA-repairing cells

The UDS assay can be conducted in vitro and in vivo. The following description briefly outlines the in vitro assay in cultured mammalian cells. After inhibition of DNA replication by serum reduction, arginine depletion, and treatment with hydroxyurea (if replicating cell lines are used), the cells are exposed to the test compound in presence of radiolabeled thymidine. Among the various cell types used, primary cultures of rat hepatocytes are often preferred to permanent cell lines, because their biotransformation capabilities are closer to those of liver cells in vivo. In addition, primary cultures of hepatocytes do not divide, so that no suppression of cell proliferation is necessary.

Radioactivity incorporation can be measured by scintillation counting of the isolated DNA or by autoradiography of whole cells. For determination of UDS in vivo, the animals are treated with the test compound and radiolabeled thymidine (most often applied by implanted minipumps). Radioactivity in DNA is determined after isolation of the DNA. Alternatively, a combined in vivo/in vitro approach may be used. In this case, in vivo treatment of the animals is followed by isolation of cells from the appropiate organs and labeling of the cells with the radioactive nucleotide in vitro. Assessment of radioactivity incorporation after in vivo treatment is usually conducted by autoradiography.

Several factors influence the interpretation of UDS data. Detection of excision repair demonstrates that the test compound has caused repairable damage to DNA, but does not answer the question whether this has any significance for the mutagenic potential of the chemical. This is very important, because measurements of UDS are averages over all cells of the study population, whereas mutation is a rare event in an individual cell. In addition, extranuclear events such as mitochondrial toxicity resulting in oxidative stress and increased production of reactive oxygen species or increased calcium concentrations in the nucleus and activation of

endonucleases may also influence indirect DNA damage and induction of UDS.

4.9.4.2. *Sister-Chromatid Exchange Test*

Sister- chromatid exchanges are reciprocal exchanges between sister chromatids thought to occur at homologous loci. Although detection of sister-chromatid exchanges can also be conducted after in vivo treatment, the test is widely applied in established cell lines in vitro (Chinese hamster cell lines, human fibroblast cell lines) and in freshly isolated human lymphocytes. Any cell type that is replicating or can be stimulated to divide can be used. The test is carried out essentially according to the following basic procedure. Cells in exponential growth are usually exposed simultaneously to 5-bromo-2′-deoxyuridine and the test compound for a period equivalent to approximately two cell cycles (incubation time depends on the cell type used). In the final 1–2 h of incubation, a spindle inhibitor (colchicine or demecolcine) is added to arrest the cells in metaphase. For detection of sister-chromatid exchanges, the two chromatids are differentially stained with a fluorescent dye such as Hoechst 33258 plus Giemsa. With this method, sister-chromatid exchanges appear as color change on one chromatid (Figure 65).

Figure 65. Sister-chromatid exchange (SCE)

The exchange is visualized by treating cells with 5-bromo-2′-deoxyuridine (BrdUrd) during two DNA replication cycles. The distribution of BrdUrd between chromatids is then determined by staining with a fluorescent dye and UV irradiation.

The sister-chromatid exchange test is one of the quickset, easiest, and most sensitive methods for detecting genetic damage. A large number of compounds have been evaluated with this method, which is usually part of the test battery for genotoxicity screening.

The problem is that the precise genetic event detected by this test is basically not known. sister-chromatid exchanges are obviously not related to chromosomal aberrations since they often fail to detect potent clastogens. They relate more to gene mutations, although there are examples of compounds that clearly induce sister-chromatid exchanges in the absence of mutations as well as the converse. Despite the uncertainty resulting from the unknown mechanism, the sister-chromatid exchange test is very useful because it detects important groups of potentially carcinogenic compounds such as alkylating agents and nucleotide analogues, as well as compounds inducing DNA single-strand breaks or acting through DNA binding.

4.9.5. *Tests for Chromosome Aberrations (Cytogenetic Assays)*

4.9.5.1. *Cytogenetic Damage and its Consequences*

In addition to gene mutations, most tumor cells investigated thus far exhibit structural and/or numerical chromosomal aberrations. Chromosomal aberrations such as deletions and translocations may result in activation of proto-oncogenes or inactivation of tumor-suppressor genes. In certain cancers of the lymphatic system (human Burkitt's lymphoma and mouse plasmocytoma), the normal proto-oncogene *c-myc*, which is involved in the regulation of cell proliferation, is translocated to the immunoglobulin locus. Immunoglobulin genes show very high transcription rates during development of B lymphocytes. The translocated *c-myc* is subjected to the same control mechanisms, resulting in inappropriately elevated expression of the gene and increased cell proliferation. In addition to these quantitative changes, chromosome aberrations may result in alterations of structure and function of cellular proteins. In many cases of human chronic myeloid leukemia, a piece of chromosome 9 carrying the proto-oncogene *c-abl* undergoes reciprocal translocation with a piece of chromosome 22. This results in joining of the proto-oncogene *c-abl* with a gene on chromosome 22 and production of a fusion protein encoded by both DNA sequences.

During cell division, chromosome segregation depends upon the functional integrity of the proteins of the spindle apparatus, that correctly divides the replicated genome into the two new nuclei. Impairment of this process, i.e. by chemical damage to the spindle apparatus, may result in nondisjunction, which means that both copies of a particular chromosome move into one daughter cell while the other receives none. Approximately 10% of the tumor types investigated so far are monosomic or trisomic for a specific chromosome. Aneuploidy is also an important cause of severe birth defects. Trisomy or monosomy of large chromosomes usually leads to early death of the embryo; trisomy of smaller chromosomes may allow the embryo to survive, but the newborn shows severe anatomical abnormalities and major physiological impairment. The most common syndrome of this group is Down's syndrome, which results from trisomy of chromosome 21.

Hence, structural and numerical chromosome aberrations may have detrimental effects on the health of the affected persons, and the following sections describe assays to detect chromosome aberrations in vitro and in vivo.

4.9.5.2. *In Vitro Cytogenetic Assays*

In the in vitro cytogenetic assays, proliferating cultured cells are treated with the test compound, and chromosomal aberrations are investigated after one or more cell cycles. Although cytogenetic assays can, in principle, be carried out in any cell type, Chinese hamster cell lines and human peripheral blood lymphocytes from healthy donors are generally used. In contrast to the spontaneously dividing Chinese hamster cell lines, peripheral blood lymphocyte cultures must be stimulated to divide by a mitogenic agent, such as phytohemagglutinin. Treatment is performed about 44 h after phytohemagglutinin stimulation, when the cells are proliferating. At least three doses of the test compound should be investigated, with the highest being in the low cytotoxic range. The usual recommendation is to treat the cells for ca. 1.5 normal cycles times, which is 15 h for Chinese hamster cells and 12–14 h for human peripheral lymphocytes. Many authors recommend longer treatment periods because some chemicals induce a mitotic delay at clastogenic doses (i.e., they increase the duration of the cell cycle). At the end of treatment, cells are induced to accumulate in the metaphase stage of mitosis with a spindle inhibitor such as colchicine or demecolcine, and at least 200 cells per treatment group are scored under the microscope for chromosomal aberrations. Chromosome breaks, fragments, and exchanges are considered specific structural aberrations, whereas gaps are usually excluded from the quantitation because the mechanism underlying their formation is not understood. Chromosome pulverization (complete fragmentation in small pieces) may also be regarded not as a parameter of clastogenicity, but rather as an indicator of severe cytotoxicity and cell death induced by the test chemical. Chemicals that are clastogenic in vitro at noncytotoxic concentrations are likely to be clastogenic in vivo. When bias resulting from lack of or insufficient biotransformation in the in vitro situation can be excluded, negative results in the in vitro assay provide a strong indication for absence of in vivo clastogenesis.

4.9.5.3. *In Vivo Cytogenetic Assays*

Induction of chromosome aberrations can be detected in intact animals either by examination of metaphases as described above for cultured cells or by the formation of micronuclei. Rats and Chinese hamsters are usually employed in metaphase analysis, while mice are commonly preferred in the widely used micronucleus test in bone marrow cells.

Rodent Micronucleus Test. The rodent micronucleus assay is an important part of the test battery for genotoxicity and is usually included in the toxicity evaluation of both pharmaceuticals and chemicals. The assessment of micronuclei is commonly conducted in polychromatic erythrocytes of bone marrow after treatment of young mice for six to eight weeks. Induction of numerical chromosome aberrations or chromosome breaks in the immature erythroblast of the bone marrow results in the formation of a micronucleus after cell division because the chromosome fragments are not participating in the chromosome segregation accomplished by the spindle apparatus. In the course of the physiological maturation of the red blood cells, the main nucleus is extruded from the erythroblast, while the micronucleus remains in the cell and can be detected in the young polychromatic erythrocyte after staining (Figure 66). The lack of nucleus in these bone marrow cells facilitates scoring for micronuclei under the microscope; however, peripheral blood cells and liver cells have also been used.

Figure 66. Mechanism of micronucleus formation in bone marrow erythroblasts

Usual treatment protocols include application of a single dose of the test compound and harvesting of bone marrow cells after 24, 48, and 72 h; or, alternatively, multiple applications (two or three doses 24 h apart) followed by a single harvest another 24 h after the last dose. The bone marrow is aspirated with a needle from the proximal end of the femur shafts and flushed with serum to obtain a homogeneous cell suspension, and after staining, the number of micronucleated immature polychromatic erythrocytes (not the number of micronuclei) is scored under a microscope. The immature erythrocytes stain bluish and can be distinguished clearly from the orange-red mature erythrocytes. Only tests with positive and negative control values within the historical control value of the laboratory are considered adequate. The minimum number of cells scored depends on the spontaneous frequency of micronuclei; 2000 cells should be scored if the control incidence is < 0.2% [172]. The ratio of polychromatic immature erythrocytes : monochromatic mature erythrocytes indicates the integrity of proliferation and differentiation processes in the bone marrow and is used as a measure of general toxicity. If the test compound has been administered at the maximum tolerated dose (as determined in the subacute toxicity test) and no increase in micronucleated erythrocytes can be detected, it is classified as negative for clastogenic activity in vivo. Clear positive results

in the in vivo assay indicate clastogenic potential also in humans.

Rodent Bone Marrow Metaphase Analysis. Metaphase analysis is usually carried out in rats at 6, 24, and 48 h after administration of a single dose or alternatively at 6 and 24 h after administration of multiple doses at 2 to 4 h prior to sampling. The animals are treated with spindle inhibitor such as colchicine and demecolcine to induce accumulation of cells in the metaphase. Metaphase analysis is much more time- consuming than scoring for micronuclei; therefore, only 50 cells per animal (500 per experiment with five male and five female animals) are usually analyzed [172]. In contrast to the rodent micronucleus test, the bone marrow metaphase analysis is not automatically included in the general screening scheme for genotoxicity; it is performed only when specific questions arise or for research purposes.

4.9.6. *Malignant Transformation of Mammalian Cells in Culture*

The term transformation in the present context means that a cultured cell line has taken on one or more morphological and/or malignant changes to give tumor cells. Among the various changes observed by exposure of cell lines to carcinogenic compounds, the following are two clearly established parameters indicating morphological transformation:

1. Inducation of anchorage independence (i.e., cells become capable of forming colonies in soft agar)
2. Loss of contact inhibition resulting in a tendency to grow in a piled-up criss-crossed pattern and to form foci

The term malignant transformation indicates that a cell line is capable of producing an invasive tumor in a suitable host. Hence, not every morphologically transformed cell line has necessarily undergone malignant transformation. On the other hand, human cancer cells are by definition malignantly transformed because they may metastasize under appropriate conditions.

The vast majority of cell transformation studies have been carried out with Syrian hamster cells [i.e., Syrian hamster embryo (SHE) cells and baby hamster kidney (BHK) cells] and with human fibroblasts.

SHE cells, isolated from 13-day-old embryos, can be induced to form piled-up criss- crossed colonies (foci) by treatment with carcinogens. Cells derived from these foci can produce tumors in athymic mice after extended subculturing (35–70 population doublings). Hence, the induction of malignantly transformed tumorigenic cells is a laborious, time- consuming procedure with several inherent problems (e.g., contamination of the plates in the course of the multiple passaging steps over several months). Therefore, the tendency developed to establish morphological transformation that can be induced in a comparatively short time as a short-term test for carcinogens. However, anchorage-independent cells showing criss- crossed growth pattern are usually not carcinogenic in animals. In addition, interlaboratory comparative elaboration studies indicated that scoring may be arduous and subjective, and in many cases the lack of dose-response and difficulties in obtaining consistently reproducible results in repeated assays may occur, even in the same laboratory [173].

Malignant transformation of cultured cells is currently an important tool to investigate the molecular mechanisms, i.e. mutations in oncogenes and tumor suppressor genes likely involved in the carcinogenic process. However, the use of cell transformation assays for screening purposes and for human risk assessment is very limited.

Two in vitro tests are required to provide a base level of information on the mutagenic potential of a chemical. These are a gene mutation test in bacteria and an in vitro mammalian cell test capable of detecting chromosome aberrations. For chemicals with significant toxicity to bacteria, an *in vitro* mammalian cell gene mutation test can be used as an alternative first test.

There are various options for selection of further test procedures in mammalian cells. An in vitro chromosome aberration test, i.e., a cytogenetic assay for structural chromosome aberrations using metaphase analysis will povide information on potential aneugenicity by recording the incidence of hyperdiploidy, polyploidy, and/or modification of mitotic index (e.g., mitotic arrest). A mouse lymphoma assay (L5178Y cells, TK locus) may detect gene mutations and structural chromosome aberrations but is not sufficiently sensitive for the detection of aneugens. These systems may be combined with an in vitro micronucleus tests, which is capable of detecting structural chromosome aberrations as well as aneuploidy.

4.9.7. *In Vivo Carcinogenicity Studies of Limited Duration*

In vivo tests of limited duration provide evidence for carcinogenicity in the whole animal in a short period (i.e., 52 weeks or less) compared to the lifelong bioassay. The experimental procedure usually involves administration of several doses of a known initiating carcinogen for a specific target organ to investigate promoting effects of the subsequently administered test compound. Alternatively, a known potent promoter for a specific tumor can be used to facilitate detection of initiating properties of the test compound. Also, many limited bioassays currently established or being developed aim to predict carcinogenicity by detecting cell lesions that consistently precede the appearance of the relevant tumor (i.e., induction of altered foci in the liver). In vivo carcinogenicity studies of limited duration are not automatically included in the usual test battery for carcinogenicity and are not accepted by regulatory authorities as a replacement for the conventional lifelong carcinogenicity study. The decision to carry out limited bioassays is made individually according to the available and required information on the test compound. Therefore, the present chapter includes only a brief description of the limited bioassays currently available.

4.9.7.1. *Induction of Altered Foci in the Rodent Liver*

In the course of rat liver carcinogenesis, cell foci exhibiting specific biochemical alterations precede the formation of liver tumors. These foci have, for example, abnormal concentrations of ϒ-glutamyl transpeptidase, glucose-6 phosphatase, adenosine triphosphatase, and the placental form of glutathione *S*-transferase and, unlike normal liver parenchyma, do not accumulate iron following iron loading. These parameters allow reliable and objective histochemical identification of preneoplastic foci as soon as three weeks after the initiation of treatment with known carcinogens. The yield is usually highest by the 12th to 16th week of exposure; therefore, the recommended approach is exposure for 12 weeks to the test compound with subcutaneous injection of iron during last two weeks to produce the iron load [174].

4.9.7.2. *Induction of Lung Tumors in Specific Sensitive Strains of Mice*

Certain strains of mice (e.g., the A/Heston) exhibit a high spontaneous incidence of lung tumors and are extremely sensitive to pulmonary carcinogens such as polycyclic aromatic hydrocarbons, certain nitrosamines, aflatoxin B_1 ethyl carbamate, hydrazines, and certain alkylating agents. The sensitivity of the test is highest 30 to 35 weeks after exposure initiation. Extension of treatment for a longer period is not recommended, because after 35 weeks the spontaneous lung tumor incidence increases rapidly in control animals as well, resulting in decreased sensitivity of the test.

4.9.7.3. *Induction of Skin Tumors in Specific Sensitive Strains of Mice*

The carcinogenic activities of several chemicals and crude mixtures can be readily revealed by their continuous application to the skin of a highly sensitive mouse strain, the Sencar mouse. Tars from coal, petroleum, or tobacco, as well as the pure polycyclic aromatic hydrocarbons and their congeners contained in such mixtures, give clearly positive results in this limited bioassay; in contrast, some arylamines and other established carcinogens do not elicit a positive response in this mouse skin test. These discrepancies are due mainly to differences in toxification or detoxification reactions between the systemic and the local applications. The mouse skin contains specific cytochrome P450 enzymes and peroxidases that can bioactivate polycyclic aromatic hydrocarbons, hence the differences in response. Therefore, this test cannot be considered a reliable predictor of the potential carcinogenicity of a xenobiotic or of human risk.

4.9.8. *Methods to Assess Primary DNA Damage*

4.9.8.1. *Alkaline Elution Techniques*

Many biochemical and analytical procedures are available to detect and quantitate the damage to DNA after contact with xenobiotics. Some of these procedures are very sensitive and thus permit detection and quantitation of DNA damage or DNA modifications after application of relevant doses of carcinogens to animals and after occupational or environmental exposure of humans.

The alkaline DNA filter elution was developed based on the observation that the rate at which large DNA single-strands pass through a membrane filter under alkaline denaturing conditions depends on the length of the strands. A broad spectrum of DNA damage types — both direct and indirect effects caused by effects of the toxicant on cellular function — can be detected with this techniques. The indirect effects include DNA single-strand breaks, DNA–protein crosslinks, and interstrand crosslinks (DNA–DNA).

The basic procedure (Fig. 67) operates essentially as follows: After treatment of cells in vitro or isolation of cells from an organ or a tissue of an animal treated in vivo, cell samples are placed onto membrane filters and lysed with a detergent- containing solution. This lysis solution is allowed to flow through the filter, thus removing most of the cellular protein and RNA, the intact DNA of cellular chromatin being retained on the filter. An elution solvent with a pH generally >12.0 is then pumped slowly through the filter to disrupt the hydrogen bonds between DNA strands. Treatment-induced DNA single-strand breaks produce DNA fragments with reduced molecular masses, thus increasing the rate at which DNA passes through the filters, whereas DNA–DNA or DNA–protein crosslinks decrease the rate compared to untreated controls. The amount of DNA eluted can be quantified either by using radiolabeled cell populations (by pretreating the cells with [^{3}H]thymidine) or by fluorogenic DNA-reactive compounds. The major limitations of the test are essentially the same as described in Section Test Systems Providing Indirect Evidence for

DNA Damage. DNA strand breaks do not necessarily indicate mutagenicity or interaction of a xenobiotic with DNA; they may also result from extranuclear damage such as increased production of reactive oxygen species due to impairment of mitochondrial functions. Hence, although a vast amount of data exists on the ability of mutagens and carcinogens to induce single-strand breaks, the test has only limited value as a screening method for mutagenicity.

Figure 67. The ^{32}P-postlabeling procedure for detection of DNA damage ($N_{mod.}$ = modified deoxynucleotide)

4.9.8.2. *Methods to Detect and Quantify DNA Modifications*

The increased sensitivity of analytical methods has resulted in the development of several sensitive and selective methods to detect and quantify modifications of DNA bases induced by xenobiotics. These methods often rely on sophisticated chromatographic techniques to separate unchanged DNA constituents from modified DNA bases.

High-performance liquid chromatography (HPLC) with fluorescence detection may be used to detect and quantify DNA adducts formed from highly fluorescent xenobiotics, such as aflatoxin$_{B1}$ and polycyclic aromatic hydrocarbons. In addition, some DNA adducts of xenobiotics are highly fluorescent, such as alkylations of the N^7 atom of guanosine [175] and cyclic derivatives formed from vinyl chloride [176]. HPLC with electrochemical detection may detect oxidative DNA modifications, such as 8-hydroxydeoxyguanosine with high sensitivity and has been used to study DNA damage by cellular aging [177].

Gas chromatography/mass spectrometry (GC-MS) techniques are widely used in the detection and quantitation of DNA modifications. After derivatization to form volatile derivatives, DNA adducts formed by methylating and ethylating agents can be detected by GC-MS with selected-ion monitoring [178]. Due to the low detection limit (attomole range), GC-MS coupled with chemical ionization and negative-ion detection (after electrophore labeling with. e.g. pentafluorobenzyl bromide) has been applied in DNA adduct monitoring [179, 180]. However, the procedures are very time consuming and prone to artefact formation. At present, due to much simpler sample workup and high sensitivity LC-MS/MS methods promise to be useful for detecting DNA modifications.

A widely used method to detect DNA adducts of bulky organic substituents, which can not be transformed to volatile derivatives, is the ^{32}P-postlabeling technique [181]. The method can be widely used because it does not require the use of radiolabeled xenobiotic and sophisticated and expensive mass spectrometry. Due to the availability of ^{32}P-labeled adenosine triphosphate with high specific activity and the possibility of concentrating DNA adducts, this procedure may detect adduct frequences as low as one adduct in 10^{10} nucleotides. The method involves isolation of DNA from an animal or cells treated with the xenobiotic, enzymatic hydrolysis of the DNA to the 3′-nucleoside monophosphates and enzymatic phosphorylation to the 3′,5′-nucleoside diphosphates with ^{32}P-labeled adenosine triphosphate as phosphate donor. The obtained mixture of ^{32}P-labeled nucleosides and modified nucleosides is then separated by multidimensional TLC. Modified nucleosides are detected by placing the TLC plates on radiation-sensitive film; quantification can be performed by liquid scintillation spectrometry after cutting the adduct spots from TLC plates. Formation of artefacts and the poor resolution of the employed TLC method are problematic.

Several procedures to detect DNA adducts based on immunological methods have also been developed. These procedures have the advantage of being rapid and simple, but they are usually selective only for a specific type of adduct and require a time-consuming procedure to generate the antibody. In addition, sensitivity is often insufficient, quantification of adducts is complicated, and cross-reactivity generates artefacts.

Modern LC-MS/MS methods have sufficiently low detection limits to detect DNA modifications in a concentration range relevant for animal toxicity studies and do not require time-consuming sample preparation. Therefore, these methods have major potential for widespread use in the detection and quantitation of DNA modifications.

4.9.9. ***Interpretation of Results Obtained in Short-Term Tests***

Although no single rule applies in every case and each test compound should be evaluated individually, some general recommendations may be useful for a reasonable interpretation of results from short-term tests. Positive results in one in vitro test for mutagenicity (i.e., the Ames test) and one in vivo test (i.e., the rodent bone marrow micronucleus assay) indicate potential carcinogenicity. The test compound is highly suspect for potential carcinogenicity if clear- cut, dose-dependent evidence for genotoxicity in more than one in vivo and one in vitro test has been obtained, especially if the compound or its metabolites are structurally alerting for DNA reactivity.

This is supported by a recent evaluation on the activity of known human carcinogens in the *Salmonella* mutagenicity test and the rodent bone marrow micronucleus test [182]. As shown in Table 34, most of the human carcinogens identified so far are positive in these popular tests. Apart from hormones, no nongenotoxic organic chemical has been shown to cause cancer in humans thus far. In contrast, since the late 1980s an increasing number of organic chemicals has emerged that are clearly carcinogenic in rodents but are not mutagenic in *Salmonella* or clastogenic in rodent bone marrow. In addition, most of these nongenotoxic rodent carcinogens (and their metabolites) do not exhibit structural alerts for DNA reactivity. The reason for the differences between the epidemiological data in humans and the chronic rodent bioassays are not known. However, these considerations also suggest that although positive results in the short-term assays for genotoxicity indicate carcinogenic potential and may give reason to interrupt further development of a compound, negative results cannot be taken as a guarantee of the absence of carcinogenic activity in vivo, but rather as a green light to proceed to the lifelong rodent bioassay.

Table 34. Mutagenicity in Salmonella typhimurium and clastogenicity in rodent bone marrow of known human carcinogens [191]

+ = positive response; (+) = predicted positive response; ND = not tested so far.
* The carcinogenic hormones (essentially natural and synthetic estrogens) and fibers (asbestos, erionite, and talc containing asbestiform fiber) are not included; the members of these groups tested so far gave negative or inconclusive results in the *Salmonella* mutagenicity and rodent bone marrow clastogenicity assays.

4.10. Evaluation of Toxic Effects on the Immune System

In the last twenty years experimental and epidemiological evidence has accumulated that the mammalian immune system may be altered (i.e. suppressed or induced) by a wide range of environmental chemicals and drugs. Well-known examples are the polychlorinated and polybrominated biphenyls; dibenzo-*p*-dioxins; benzene; isocyanates; metals such as chromium, lead, and nickel; and organometallics such as di-*n*-octyltin chloride and tri-*n*-butyltin oxide.

Immunotoxicity is the ability of a substance to adversely affect the immune system: the immune response of affected individuals is altered. Immunotoxic responses may occur when the immune system is the target of the chemical insult; this in turn can result in either immunosuppression and a subsequent decreased resistance to infection and certain forms of neoplasia, or immune disregulation, which exacerbates allergy or autoimmunity. Alternatively, toxicity may arise when the immune system responds to an antigenic specificity of the chemical as part of a specific immune response (i.e., allergy or autoimmunity). Changes in immunological parameters may also be a secondary response to stress resulting from effects on other organ systems. Therefore, it must be recognized that in principle all chemical substances may be able to influence parameters of the immune system if administered at sufficiently high dosages. However, an immunotoxic effect should only be discounted when a thorough investigation has been performed. Although the immune system is considered as a target organ with regard to systemic toxicology, it consists of several different organ systems. A very large number of different cell types, present in practically all tissues and compartments of the human or animal body, participate in the immune response. Due to the complexity, it is not possible to describe the immune system in the context of the present chapter. Only a very brief description will be given to help the understanding of the current practical approaches of the evaluation of adverse effects on immune function induced by chemicals (see also ⟶ Immunotherapy and Vaccines – Introduction).

The overall immune system can be categorized in two major subsystems: the humoral and the cell-mediated subsystems. The effects of the humoral system are mediated by B lymphocytes producing antibodies that react with antigenic (usually foreign) material (i.e., antibodies attack bacteria and viruses before they can enter the host cell). The cell-mediated system involves primarily the mobilization of phagocytic leucocytes (macrophages) to ingest foreign organisms such as bacteria and the activation of T lymphocytes.

The two systems do not function independently in different situations; rather, they interact by complex feedback mechanisms that are only partly understood. One of the main properties of the immune system is the rapid production of a large number of cells capable to react with a specific antigen when this antigen is presented (again) to the organism. This important property is based on the presence of a wide variety of memory cells that were specifically adapted to the antigen at the time of initial contact.

Immunocompetent cells are required for host resistance, and thus exposure to immunotoxicants can result in increased susceptibility to any type of toxicity and disease including cancer.

The evaluation of adverse effects on the immune system can be carried out in two tiers [183, 184]. The first tier evaluates immune-related parameters (haematology, blood chemistry, organ weights and histopathology) that are included in revised standard testing protocols of repeated-dose (28 and 90 d) toxicity studies (Table 35).

Table 35. Immunological parameters that can be included in repeated-dose toxicity studies in rats for compounds for which no prior immunotoxic potential has been identified (tier I)

Parameters assessed	Tests
Hematology and blood chemistry	differential white blood cell counts
	bone marrow cellularity
	albumin : globulin ratio
	serum immunoglobulin classes
Organ weights	thymus, spleen, lymph nodes
Histopathology	thymus, spleen, lymph nodes, bone marrow, Peyer's patches (if oral administration)
	bronchus-associated lymphoid tissue (in case of pulmonary administration)

Compounds showing some immunotoxic properties in this first tier and also chemicals suspected of having immunotoxic effects based on information from prior studies or structure–activity relationships are further evaluated by functional assays that assess competence of immune cells (Table 36) For a detailed description of the experimental procedures see [196].

Table 36. Selected functional assays to assess immunotoxicity of compounds for which some immunotoxic properties have been implied in tier I evaluation (see Table 35) or in prior studies (tier II)

Parameter assessed	Tests
Cell-mediated immunity	mixed leukocyte response to antigenic determinants; induction of cell proliferation by the T-lymphocyte mitogen concanavalin A; T-lymphocyte cytotoxicity; delayed hypersensitivity response (DHR) to keyhole limpet hemocyanin (in contrast to the first three assays, that are carried out in cultured cells in vitro, the DHR is induced in vivo)
Antibody-mediated	antibody plaque-forming cell response; serum antibody titer after exposure to specific antigens determined by enzyme-linked immunosorbent assay (ELISA)

immunity	
Natural and induced host resistance	natural killer cell cytotoxicity; macrophage-mediated phagocytosis and intracellular killing; assessment of macrophage and T-lymphocyte competence by inoculation of *Listeria monocytogenes*; host resistance to melanoma cells

4.11. Toxicological Evaluation of the Nervous System

Neurotoxicity is the induction by a chemical of adverse effects in the central or peripheral nervous system, or in sensory organs. It is useful for the purpose of hazard and risk assessment to differentiate effects specific to sensory organs from other effects which lie within the nervous system. A substance is considered neurotoxic if it induces a reproducible lesion in the nervous system or a reproducible pattern of neural dysfunction.

The identification and characterization of neurotoxic properties of chemicals is one of the essential goals of every toxicity screening programm. Neurotoxicity has traditionally been associated with structural pathological modification of nervous system constituents (i.e. neurons, glial cells, and endothelial cells). Hence, the most important tool to assess neurotoxic effects in the past has been the histopathological examination of the nervous system of animals acutely or chronically exposed to xenobiotics. Over the last ten or twenty years, however, several reasons have called for the development and use of functional tests in neurotoxicity screening. First, detailed histopathological analysis of the nervous system is very time-consuming and requires experienced neuropathologists. Second, many chemical compounds disturb the nervous system without causing identifiable structural lesions. This clear need for functional tests to assess neurotoxicity has led to the development of a functional observational battery and an automated test to detect locomotor activity in rats based on methods that have been used by neuropharmacologists for many decades for the evaluation of psychoactive neurologic and autonomic pharmaceutical compounds.

4.11.1. *Functional Observational Battery*

The functional observational battery can be carried out both in acute and repeated-dose toxicity studies. The sequence of tests is usually arranged to progress from the least to the most interactive with the animal. The assessment begins with home cage observations followed by measurement made while handling the animals and assessment of activities in the open field. Assessment of reflexes, as well as physiologic and neuromuscular parameters is carried out at the end of the examination. Specific parameters assessed at these different stages are summarized in Table 37, and more detailed descriptions of some important tests are given below (reviews: [197-199]).

Table 37. General parts of the functional observational battery to assess neurotoxicity and specific examples of parameters recorded

A.	home cage observations	posture
		palpebral closure (eyelids wide open to completely shut)
		convulsions (clonic, tonic)
		biting
B.	observations while handling the animal	ease of removal from cage and of handling in hand, lacrimation, salivation, piloerection, fur appearance
C.	open-field activity (observations over 3-min period)	time to first step
		number of rears (supported and unsupported)
		number of urine pools and defacations
		mobility and gait
		tremors, ataxic gait, convulsions
D.	reflexes	approach response (e.g., to a pencil)
		touch response
		click response
		tail response
		pupil and eye blink response
		forelimb and hindlimb extension
		righting reflex: hold rat in supine position, drop from approximately 30 cm and note ease of landing
E	physiologic observations	catalepsy
		body temperature
		body weight
F	neuromuscular observations	rotarod performance grip strength
		hindlimb extension strength
		hindlimb foot splay

Catalepsy. Catelpsy can be measured by placing the rat on four corks (35 mm high, 40 mm in diameter, 100 mm between fore- and hindfeet, 60 mm between right and left feet). Duration of immobility at this position is measured for a period up to 60 s. For the assessment of catalepsy, a number of experimental modifications exist (i.e. placing the rats on a horizontal bar 12 cm above the ground). However, the four-corks procedure allows the best distinction between cataleptic and heavily sedated animals.

Grip Strength. The rat is allowed to grip a triangular ring with its forepaws and is pulled back along a platform until its grip is broken. As the pulling back continues, the animal's hindpaws reach a T-shaped rear limb grip bar, which it is allowed to grasp and then forced to release by continued pulling. Special devices are used to measure the maximum strain required to break forelimb and hindlimb grip.

Rotarod Performance (Rotating-Rod Test). This test requires preliminary training of the animals to walk on a rotating rod (7 cm in diameter, 5–12 rpm rotation rate). During the training period, the containers underneath the rod are filled with water to prevent the rats from jumping off. For testing, the time each rat remains on the rotarod is measured up to 2 or 3 min. Due to its objectivity and reproducibility this test is one of the most popular for the evaluation of adverse effects to the nervous system.

Hindlimb Foot Splay. The hind feet are painted, animals are dropped from a horizontal position 30 cm above a table onto paper and the distance between the middle of the ink spots is measured.

4.11.2. *Locomotor Activity*

Locomotor activity is not automatically part of the screening battery for neurotoxicity, the decision to carry out the test being rather made individually based on preliminary observations. Locomotor activity is assessed in special test chambers using a photocell detection procedure. Animal movement inside the chamber interrupts the photobeams and is translated into activity counts. Data on animal activity are usually recorded over three 5 min intervals.

In addition, a number of further methods to investigate neurotoxicity are available and standardized approach for an evaluation may not be given, but need to be decided on a case-by-case basis (Table 38).

Table 38. Methods for investigation of neurotoxicity

Effect	Methods available
Morphological changes	Neuropathology

	Gross anatomical techniques
	Immunochemistry
	Special strains
Physiological changes	Electrophysiology (e.g. nerve conduction velocity, NCV)
	Electroencephalogram (EEG, evoked potentials)
Behavioral changes	Functional observations
	Sensory function tests
	Motor function tests (e.g., locomotor activity)
	Cognitive function tests
Biochemical changes	Neurotransmitter analyses
	Enzyme/protein activity
	Measures of cell integrity

A major problem in neurotoxicity screening is that the general behaviour of rats is not stable and uniform, even when they are kept under strictly controlled conditions and not exposed to neurotoxic compounds. Therefore, many authors suggest to carry out the tests without knowledge of the treatment protocols. Furthermore, since many observations are subjective, it is important to use experienced and well trained scientists and technicians in the evaluation.

4.12. Effects on the Endocrine System

Although endocrine disruption is often regarded as a specific end point in toxicity testing, it is just a mechanism by which a chemical may induce adverse effects. Many endocrine-dependent toxicities will be detected in the course of the already available methods for toxicity testing. However, a number of specific tests for endocrine effects of chemicals are under discussion for introduction into toxicity testing.

The endocrine system consists of a number of glands such as the thyroid, gonads, and the adrenals, and the hormones they produce such as thyroxine, oestrogen, testosterone and adrenaline. These hormones may influence development, growth, reproduction and behaviour of animals and humans.

Endocrine disrupters are defined as:
- Chemicals that have properties that might be expected to lead to endocrine disruption in an intact organism, its progeny, or (sub)populations
- Chemicals that alter functions(s) of the endocrine system and consequently may cause adverse health effects in an intact organism or its progeny

Endocrine disrupters may to interfere with the endocrine system by several mechanisms:
- By mimicking the action of a naturally produced hormone such as oestrogen or testosterone and thereby inducing similar chemical reactions in the body
- By blocking the hormone receptors in cells and thus preventing the action of normal hormones;
- By affecting the synthesis, transport, metabolism, and excretion of hormones and thus altering their concentrations.

A variety of test systems to characterize the potential of chemicals for endocrine disruption, ranging from receptor-binding assays to complex in vivo measurements, have been proposed, but a specific testing approach has not yet been agreed.

Some testing guidelines (e.g., the 28-d study guideline) detect effects on endocrine function, but there are no test strategies/methods available which can detect all possible effects that may be linked to the endocrine disruption mechanism.

[Top of Page]

5. Evaluation of Toxic Effects

One of the major environmental and occupational issues of concern to both scientists and administrators is the control of potential health hazards to humans due to the production, use, and disposal of chemicals. The concern arises from the increasing numbers of chemicals in production and use and the increasing numbers of chemicals demonstrated to exert toxic effects in one or several of the sensitive toxicity testing systems available. This situation has afforded growing legislative control of the production and application of chemicals to ensure adequate protection of human health. Control measures based on the recognition of potential adverse health effects may limit the presence of hazardous chemicals in the environment or regulate the use of hazardous chemicals, thus reducing the potential health risks to humans (Table 39).

Table 39. Possible measures to reduce human exposure to hazardous chemicals

Application or exposure to chemical in question	Measures to reduce exposure
Industrial chemicals	reduction or cessation of application; protective measures in the workplace; alternative chemicals with lower hazard
Pharmaceuticals	cost – benefit analysis
Alcohol, smoking, drugs of abuse	education
Environmental chemicals	quantitation of exposure, strategies for avoidance or reduction of environmental pollution

The assessment of potential human health risks resulting from the exposure to chemicals provides the basis for appropriate regulatory and control measures. The health risk assessment determines whether a xenobiotic may cause adverse health effects, at what level and frequency of exposure, and the probability that adverse health effects will occur. The term “risk assessment” is increasingly used in the context of potentially toxic chemicals. Scientific risk assessment considers the available data on the toxicology of a specific chemical when judging which agents potentially pose a significant risk to the human population. Toxicology focuses on the identification and quantitation of potential hazards by using animal studies as surrogates for humans. Permissible exposure levels for humans are derived from the results of the animal studies by using margins of safety or defining “acceptable” incidences of adverse health effects in exposed humans [185].

Health risk assessment and its use in regulatory decisions have recently generated intense controversy. The debate over risk assessment is politically and emotionally charged, and creates an adverse atmosphere heightened by the extraordinary sums of money at stake. Industry complains that the costs of complying with possible overregulation based on inappropriate risk assessments may be excessive; moreover, lawsuits on potential environmentally caused diseases, especially in the United States, involve huge sums of money. On the other hand, environmentalists claim that risk assessment practices and policies do not adequately protect human health; moreover, health care costs for the treatment of environmentally caused diseases may also be very high. These considerations have led to an intensive rethinking of the health risk assessment process and have increased the awareness that in many cases, the scientific foundation for risk assessment is weak. This rethinking led to the conclusion that resolution of the controversies by the development of effective prevention strategies and rational priority setting may be achieved only by strengthening the scientific background and available data by research and by developing better methods to estimate risks due to chemical exposures [185-187].

Before considering the practice of health risk assessment, several terms frequently used and misused in risk assessment and its perception should be clarified. In discussions on health effects of potentially toxic chemicals, the terms “hazard” and “risk” are often used with an identical meaning, although they are clearly different. Hazard defines the intrinsic toxicity of a chemical and is not identical to risk. Risk is the estimated or measured probability of injury or death resulting from exposure to a specific chemical. Risk may be described either in semiquantitative terms such as high or low risk or in quantitative terms such as one person experiencing an adverse effect per 10 000 persons exposed. Risk may also be described in absolute terms (probability of adverse effects due to a specific chemical exposure) or in comparative terms by comparing the probability of adverse effects between a population exposed to an agent and an unexposed population.

The health risks due to the contact with potentially toxic chemicals are dependent on the conditions of exposure, since not only the intrinsic toxicity of a chemical determines the magnitude ot the adverse effect but also the dose. As noted in Chapter 1, the magnitude of the toxic effects is the product of the intrinsic toxicity of a chemical multiplied by the dose taken up by exposed animals or humans; thus, all toxic effects are dose-dependent and even very toxic chemicals may not cause toxic effects when the dose is low. If the dose is zero, despite a very high intrinsic toxicity of a specific chemical, the toxic effect and the risk of adverse health effects will be zero. On the other hand, chemicals with low intrinsic toxicity may induce toxic effects when the dose is high and may thus pose a significant risk. In toxicological terms, risk is therefore the product of the intrinsic toxicity of a chemical and the exposure characteristics.

5.1. Acceptable risk, Comparison of Risks, and Establishing Acceptable Levels of Risk

In earlier phases of risk assessment, the basic belief was that few chemicals are toxic and all of these toxic chemicals are derived from synthetic processes. To achieve a zero risk, chemical exposure must be reduced below a threshold level, under which it causes absolutely no risk. However, where such a threshold cannot be demonstrated, one must assume that a finite risk may occur at any exposure level, consequently, absolute control of risk is possible only if the source of exposure is eliminated altogether. These considerations resulted in the zero-risk concept. The Delaney Clause of the Federal Food and Drug Act in the United States is an example of a zero-risk approach in the regulation of food additives. This law states that no xenobiotic whose carcinogenic potency in animals has been demonstrated may be used as a food additive.

However, the more widespread testing of chemicals for toxicity, the increased sensitivity of analytical instruments to determine chemicals in the environment and at the workplace, and the developments in the science of toxicology put the basic assumption of the zero risk concept — that is, only synthetic chemicals are toxic — into question.

However, the more widespread testing of chemicals for toxicity, the increased sensitivity of analytical instruments to detect chemicals in the environment and the workplace, and developments in the science of toxicology put the basic assumption of the zero-risk concept — that only synthetic chemicals are toxic — in question. These developments led to the recognition that zero risk was unachievable and, perhaps, unnecessary for the regulation of chemicals. The observation was based mainly on a few facts: (1) all chemicals, both of synthetic and natural origin, are toxic under specific exposure conditions; (2) most of the hazardous chemicals routinely encountered by humans are of natural rather than synthetic origin; (3) most of the exposure to hazardous synthetic chemicals cannot be avoided entirely or be eliminated from the environment without changing profoundly the way of life in many countries; and (4) in the case of cancer risk assessment, DNA damage and mutations, assumed to be of major significance in the process of carcinogenesis, occur spontaneously, albeit at a low rate. Examples of endogenously occurring DNA damage are hydrolytic deamination, depurination, oxidative modification, and endogenously formed DNA adducts. Well-known examples of hazardous synthetic chemicals are benzene, which is present in the environment as a result of its emission from motor vehicles, cigarette smoking, and other sources, or 2,3,7,8-tetrachlorodibenzodioxin formed in forest fires. The effect of naturally occurring chemicals and chemical exposure due to life-style factors is best exemplified by the estimated contribution of different factors to the incidence of avoidable cancers in humans (Fig. 68).

Figure 68. Contribution of chemical exposure and life-style factors to the incidence of avoidable cancer in human [200]

According to the large epidemiological study of DOLL and PETO (1981), natural chemicals in diet and chemicals inhaled by cigarette smoking are the major causative agents in human cancer. Occupational and environmental exposure to synthetic chemicals constitutes only a minor causative factor.

Given these facts, the acceptable risk concept was developed as an alternative. The acceptable risk concept realizes that it is not possible to eliminate all potential health risks associated with chemical exposure due to the life style. According to the concept of acceptable risk, safety — the reciprocal of risk — is no longer an absolute term but is redefined as a condition of certain, but very low and thus acceptable, risk. This conceptual change improves the ability to deal with potentially very low risks identified by the increased sensitivity of analytical instrumentation and with increasingly sensitive scientific methods to detect potential adverse effects of xenobiotics. The concept of acceptable risk also permits the definition of limits for the exposure to toxic chemicals that can be considered to have a negligible impact on the incidence of adverse effects in an exposed population. Risk assessment is therefore unavoidable and must implicitly or explicitly involve a balance of risk and benefit [185-189]. Some of the main factors considered in establishing acceptable risk levels for exposure to a chemical follow:

- **Beneficial aspects**
  - Economic growth
  - Employment
  - Increased standard of living
  - Increased quality of life
  - Taxes generated

- **Detrimental aspects**
  - Decreased quality of life
  - Health effects
  - Lawsuits
  - Loss of environmental resources
  - Loss of work
  - Medical expenses

5.2. The Risk Assessment Process

Several individual elements make up the risk assessment process. In the first step, the potential adverse health effects of a chemical, a mixture of chemicals or a specific technical process are evaluated by the application of toxicity tests (for details, see Chap. 4) and, if the chemical is already in widespread use and humans are exposed, by considering the data from epidemiological studies. The second step in risk assessment determines the dose–response for the observed adverse effects. In parallel, the exposure of humans to this xenobiotic is quantitated by analytical procedures or, if the chemical is not yet in widespread use, by the estimation of likely exposure scenarios. In the third step, the results obtained in the toxicity studies are extrapolated. This involves an extrapolation both from adverse effects seen in experimental animals to humans, and often an extrapolation from the effects seen after high doses in animals to the much lower doses humans usually encounter. The last step of risk assessment, risk characterization, involves the combination of steps one to three to judge the existence and magnitude of the public health problem and characterizes the uncertainties inherent in the risk assessment process

5.2.1. *Hazard Identification Techniques*

Hazard identification is the step in which the adverse effects of the xenobiotic are determined. Evaluation of both acute and chronic toxicity is performed by using animals as experimental models for humans. The use of animals as surrogate for humans is based on the following assumptions: (1) xenobiotics with a likely adverse effect in humans will manifest some degree of toxicity in other living systems when the dose is sufficiently high; (2) if a sufficient number of animal species are dosed with the xenobiotic, at least one should exhibit a similar pattern of biotransformation and toxicokinetics to that seen in humans; and (3) if a sufficient number of different animal species are dosed with the xenobiotic, at least one is likely to exhibit the toxic responses and clinical symptoms occurring in humans.

Typical end points in studies aimed at hazard identification in intact animals include mortality, reproductive and developmental effects, target organ toxicity, and cancer. Hazard identification studies at present also include the determination of a range of biochemical end points related to specific toxic effects such as toxicokinetics, routes and extent of biotransformation, structure of reactive intermediates, and binding of reactive intermediates to cellular macromolecules. In addition, many short-term tests for specific toxic effects such as DNA damage, mutagenicity, or clastogenicity are increasingly included in hazard identification procedures.

The acute toxicity of xenobiotics is evaluated by a number of procedures from which the LD_{50} may be calculated. With the more recently recommended fixed-dose method information on target organs affected and types of toxic effects may also be obtained. Repeated-dose toxicity studies last between two weeks (subacute toxicity studies) and 6–24 months (chronic toxicity studies), the lifespan of the animals, including post-mortem examination, histopathology, clinical chemistry, and

hematology at termination and at specified time points during the study. From the chronic toxicity studies, the lowest observed effect level (LOEL), also referred to as the lowest observed adverse-effect level (LOAEL), and the no observed effect level (NOEL) are obtained for noncancer endpoints. The NOEL is the highest does administered that does not induce observable toxic effects. The NOEL may not be identical to the no-effect level if insensitive methods are applied or the wrong end point is chosen. Moreover, the value obtained for the NOEL will depend on the number of animals used in the study and the spacing of the applied doses.

Short-Term Tests for Specific Toxic Effects In Vivo and In Vitro. A variety of short-term tests has been developed for the detection and quantification of toxic effects. Most of the more established and well-evaluated test systems are designed to evaluate the genotoxic activities of xenobiotics and employ well-defined genetic changes (DNA damage, gene mutations, chromosome defects, cell transformation) in prokaryotes, lower eukaryotes, and mammalian cells. Knowledge that a genotoxic chemical is active in vivo in the target organ of carcinogenesis enhances confidence that the genotoxicity of the chemical is important in the process of cancer induction by that chemical. Before any short-term test can be used with confidence to assess potential toxic effects, its validity should be thoroughly evaluated and its major drawbacks should be explicitly noted. Moreover, it should be kept in mind that most available short-term tests are well designed to give qualitative information and their major use for risk assessment purposes is therefore the confirmation or exclusion of a specific toxic response. The magnitude of toxic response in intact animals or humans depends on both toxicokinetics and toxicodynamics. The toxicokinetic phase of the toxic response is not considered in most of the in vitro short-term tests. Therefore, short-term tests in vitro may be used for hazard identification only in combination with studies on adverse effects in animals and studies on the toxicokinetics of a xenobiotic.

Biotransformation and Toxicokinetics. Studies on the extent of biotransformation including structural identification of the metabolites formed from the xenobiotic both in intact animals and in appropriate in vitro systems such as organ homogenates or fractions with enzymatic activity also contribute to hazard identification [190]. The structures of metabolites formed and the presence and extent of covalent binding of metabolites to macromolecules such as protein and DNA indicate the formation of electrophilic metabolites and thus a potential hazard.

For example, the structure of excreted mercapturic acids may give information on the structure and reactivity of the electrophilic metabolite and sites of cellular interactions [191]. Information on the rate of absorption and elimination may indicate a possible accumulation of the xenobiotic in humans, with the consequence of potential adverse effects. These studies should be performed on at least two animal species in vivo. For in vitro studies, human tissue samples should be included to confirm that biotransformation reactions are identical to those, observed in animals occur in humans. Different mechanisms of toxicity may operate at different dose levels; in these instances, toxicokinetic data may help in understanding dose-dependent mechanistic differences. The toxicokinetics of a xenobiotic in humans may be extrapolated by physiologically based pharmacokinetic models from the results obtained in experimental animals. Information on potential pathways of biotransformation may also be made by computerized structure analysis of the xenobiotics with specific computer programs [147, 192]. These are designed for predicting routes and rates of biotransformation based on the presence of functional groups in the molecule; however, at present, the available programs are far from perfect, and they should only be used in conjunction with expertise and as a basis for experimental planning.

Structure–Activity Relationships and Chemical Structure Analysis. Predictive data on the potential of xenobiotics, mainly organic chemicals, to induce adverse effects may be derived from relationships between chemical structure (physicochemical properties, presence of functional groups, atomic configuration) and biological activity, termed structure–activity relationships.

Two approaches to hazard prediction utilize structure–activity relationships. The first is essentially a qualitative approach and involves the comparison of the structure of the xenobiotic with that of other compounds already known to cause specific toxic effects. The comparison with known structures and the knowledge of biotransformation reactions and mechanisms of toxicity permits the identification of toxophores in the structure of xenobiotics. Toxophores are functional groups present in the molecule which are likely converted to toxic metabolites or posess chemical reactivity related to mechanisms of toxicity. Examples of toxophores are olefinic moieties, which may be oxidized to epoxides, and terminal carbon atoms in aliphatics bearing two halogen atoms, which may be oxidized to acyl halides. The scope and usefulness of structure–activity relationships depend on the availability of a sufficiently large database on the toxic effects of chemicals with common subgroups and structures [147], [192]. The main limitation of this approach is the qualitative nature of the resulting estimate of potential toxicity. The second approach involves quantitative structure–activity relationships and relies on the computer-aided analysis of databases on toxic effects of chemicals. A basic feature of the applied techniques is the use of pattern-recognition schemes or substituent weighting factors coupled with regression analysis. Some useful predictions have been made with these techniques, but due to the complex nature of toxic effects and the multitude of factors governing the toxic response, there are still severe limitations to the applicability of quantitative structure–activity relationships for predicting toxicity profiles.

Clinical and Epidemiological Studies. In principle, the best evidence for the toxic effects of a chemical in humans is derived from clinical and epidemiological studies. These studies assess effects in the species of interest for risk assessment and at relevant concentrations. Potentially confounding extrapolations from high to low dose and from animals to humans are not required. However, several weaknesses limit the applicability of these studies to hazard identification. In most cases, reliable exposure data are lacking, consequently, dose–response relationships cannot be established. In addition, the sensitivity of epidemiological studies to detect health problems is comparatively low. Unless the toxic effect of a particular xenobiotic is very unusual in control (unexposed) groups, it may pass unnoticed in a normal survey. Examples are the identification of asbestos exposure as a cause of mesothelioma or vinyl chloride as a cause of hemangiosarcoma, very rare forms of cancer in humans not exposed to asbestos or vinyl chloride, respectively. Moreover, the results of epidemiological studies, especially on cancer risk, may reflect the risk associated with exposure to chemicals decades ago because of the long latency period. Other limitations are confounding variables such as smoking and concomitant exposure to other xenobiotics, which often impair the interpretation of carcinogenicity data in humans. Thus, evidence based on epidemiological observations has identified only a limited number of chemicals as human carcinogens; many of the identified compounds are used in cancer chemotherapy and have the intrinsic property of genotoxicity (Table 40).

Table 40. Examples of established human carcinogens based on epidemiological observations

Chemical or agent	Site of tumor formation
Aflatoxin	liver
Alcoholic drinks	mouth, esophagus
4-Aminobiphenyl	bladder
Benzidine	bladder
2-Naphthylamine	bladder
Arsenic	skin, lung
Asbestos	lung, pleura, peritoneum
Azathioprine	reticuloendothelial system
Benzene	bone marrow
Bis(chloromethyl) ether	lung
Cadmium	prostate
Chlorambucil	bone marrow
Chlornaphazine	bladder
Chromium	lung
Cyclophosphamide	bladder
Bis(2-chloroethyl) sulfide	larynx, lung
Nickel compounds	nasal cavity, lung
Estrogens	endometrium, vagina
Phenacetin	kidney and lower urinary tract
Polycyclic aromatic hydrocarbons	skin, scrotum, lung
Steroid hormones	liver
Tobacco	mouth, pharynx, larynx, esophagus, lung, bladder
Vinyl chloride	liver

5.2.2. *Determination of Exposure*

The quantification of exposure, both in individuals and in populations, is a prerequisite for the quantification of risk. Reliable data on exposure are needed to assess the adverse effects of the xenobiotic and to recognize specific risk factors such as occupation, life style, and social status. The dimensions of exposure include

intensity, frequency, route, and duration; in addition, the nature, size, and makeup of the exposed population should be characterized. The assessment of exposure is a difficult and complex task, and is often neglected. Typically, estimations and field measurements are required. The estimation of human exposure to a particular xenobiotic involves an initial estimation of the possible sources of the chemical and the possibilities for exposure. A good inventory of sources may provide important information on critical pathways of exposure, populations at particular risk, and the levels of exposure.

In many cases, the duration and level of exposure, especially after chronic contact, may only be estimated from ambient levels of the xenobiotic in the environment, and estimations may thus be crude; owing to the large numbers of potentially exposed persons, only in special situations (e.g., occupational exposure, after disasters), will exposure data, including determination of the internal dose, be available.

Specific procedures to detect exposure to a certain xenobiotic and procedures to estimate exposure by determining biological effects may be used. These include:

- Direct measurement of the chemical in environmental samples such as water, air, and soil.
- Measurement of the chemical, its metabolites or products of the interaction of the chemical or its biotransformation products with cellular macromolecules (protein and/or DNA) in body fluids and tissues (biomonitoring).

Biological end points in exposure assessment may be:

- Assessment of biochemical indicators for specific adverse effects known to be caused by the xenobiotic, e.g., inhibition of specific enzymes such as cholinesterase activity in persons exposed to organophosphate pesticides.
- Observation of pathological evidence of exposure such as cytogenetic changes in lymphocytes from workers exposed to chromosome-damaging chemicals at the workplace. However, the use of biological end points for exposure assessment lacks the resolving power to discriminate between endogenous changes and the effects of xenobiotics, and therefore chemical specific indices of exposure should be favored for quantitation of exposure [178, 193].

Due to the time-consuming and cost- and labor-intensive procedures required, data on exposure to xenobiotics are usually limited. Difficulties in identifying concomitant exposures, interactions with other xenobiotics or activities, special risk groups such as the very old or very young and pregnant women, and patterns of exposure result in a high degree of uncertainty in exposure assessment in human populations.

A stepwise approach to exposure assessment using the following hierarchy can be applied. The most reliable exposure assessments are based on measured data, including the quantification of key exposure determinants. When these are not available, appropriate surrogate data may be used. Modeling may also be used in the absence of useful data, but the limitations of the modeling approach should be clearly stated.

5.2.3. *Dose-Response Relationships*

The establishment of the dose–response relationship for adverse effects in animals is the decisive step in risk assessment. This step quantifies the relationship between received or administered dose and biological response and may be performed on an individual or population basis. Dose–response assessment includes exposure intensity and duration and factors modifying toxic response such as sex, age, health status, and route of administration. Since the dose–response assessment can only rarely be performed in humans, extrapolation from data obtained in animals to humans is usually required. Moreover, many animal experiments, particularly carcinogenicity bioassays, are performed with high doses to increase the sensitivity of the assay. Therefore, besides species extrapolation, an extrapolation from effects seen after high doses in animals to the low doses usually encountered by humans is necessary. This extrapolation step from high, sometimes toxic doses in animals to low doses in humans is controversial.

The extrapolations form high to low dose are performed differently depending on the type of toxic response elicited by the xenobiotic. As explained in Chapter 1, toxic effects of a chemical may be caused by both reversible and irreversible interactions of the xenobiotic or its metabolite(s) with macromolecules in the organism. Many acute toxic responses such as carbon monoxide poisoning are based on reversible interactions and are associated with thresholds. Threshold doses are doses below which the probability of a response is zero. The biological basis for thresholds is well founded and may be demonstrated on a mechanistic basis. On the other hand, many chronic toxic responses, particulary chemical carcinogenesis, are often considered nonthreshold effects. Since a negative can never be proven, the absence of thresholds cannot be demonstrated by experiments and is based on consideration of the mechanisms of chemical carcinogenesis. Different approaches have thus been developed in establishing acceptable levels of exposure to threshold and nonthreshold responses (see below).

5.2.4. *Risk Characterization*

The hazard identification, the exposure assessment, and the dose–response assessment merge into risk characterisation. Risk characterisation estimates the incidence of expected adverse health effects in exposed populations. As noted in Section Hazard Identification Techniques, risk characterization and the establishment of acceptable exposure levels are handled differently for carcinogenic and noncarcinogenic xenobiotics. For chemicals that cause adverse effects by mechanisms with thresholds, the safety factor approach was developed. For nonthreshold responses such as cancer, both quantitative and qualitative risk assessment procedures are used.

5.2.4.1. *The Safety-Factor Methodology*

When the safety assessment of a chemical is based on animal toxicity testing, a different evaluation of the data is required compared to safety evaluations relying primarily on human observations. Since animal experiments to determine health hazards of chemicals were widely used in the 1940s and human health risks had to be extrapolated from these data, the idea of a safety factor, which was to be applied to the results from animal studies, was developed. The safety factor approach was first proposed in the 1950s by ARNOLD LEHMANN of the FDA as a protective measure for human health and is intended to compensate for uncertainties in the extrapolations of animal data to humans. This concept was applied to the determination of acceptable daily intakes (ADIs) by the World Health Organization from the 1960s onward. The ADI was defined as “the daily intake of a chemical which, during an entire lifetime, appears to be without appreciable risk on the basis of all known facts at that time.”

The safety factor, or as it is sometimes called, the uncertainty factor, has been introduced to consider both interspecies and interindividual differences in response to potential toxic effects of the chemical under consideration. The major purpose of the safety factor is the protection of human health by establishing safe exposure levels; the exposure levels defined do not mean that exposure above these levels will result in adverse effects. Despite several limitations and criticisms, the safety factor approach has been used for many years in Western Europe and the United States, and has proven useful and reliable. It was thus adopted internationally as the standard procedure for assessing the ADI.

This risk assessement approach is based on the establishment of a point of departure for the required extrapolation, which may be an NOEL or NOAEL or a benchmark dose (e.g. ED_{05}) in animal studies on chronic toxicity, and then defining permissible human exposures by the application of a safety factor. In this context, the NOEL is defined as the lowest dose of the xenobiotic in an animal experiment which produced no detectable effect in the most sensitive animal species treated. Once a NOEL has been determined, a safety factor for human exposure is introduced and, often, a permissible level of exposure of one hundredth of the NOEL in animals is defined for humans. The 100-fold safety factor is justified on the basis of a 10-fold difference to reflect an interspecies difference in susceptibility and a 10-fold difference to reflect possible interindividual variations in susceptibility in humans [188]. The acceptable daily intake is then obtained by dividing the NOEL from the study by the safety factor.

The safety-factor approach assumes that toxic effects exerted by the chemical exhibit a dose–response curve with a threshold, that the results of the toxicity studies in animals are relevant to humans, and that extrapolation of the dose is reliable.

A similar approach is the margin-of-safety (MOS) approach which determines by how much the derived NOAEL exceeds the determined or estimated exposure. The size of the MOS (< 100 or > 100) determines the extent of concern of a specific exposure.

As noted above, safety factors of 100 are frequently applied. However, when reliable data for adverse effects of the chemicals in humans are available, a safety factor of only 10 may be applied. On the other hand, a safety factor of more than 100 is appropriate when no or only limited data on the toxicity of the chemical in animals are available. Note that the safety factor is not based on scientific evidence. Additional data on the mechanisms of toxic effects in animals and on the toxicokinetics and biotransformation of the xenobiotic in animals and humans are required and add scientific credibility to the proposed safety factors. Therefore, the choice of a safety factor should consider, in addition to the NOEL, a series of further qualitative parameters:

•Evaluation of animal toxicity studies

- Number of studies and effects observed
- Type of toxic effects
- Time course for toxic effects
- Tumorigenicity

•Evaluation of biochemical end points
- Biotransformation and toxicokinetics
- Mechanism of action, covalent binding to macromolecules
- Short-term test for genotoxicity and other nonthreshold effects

•Evaluation of species differences
- Interspecies variations in biotransformation and toxicokinetics
- Influence on anatomical and physiological differences of toxic effects between species

Application of the most appropiate safety factor requires careful analysis of the data available on the toxic effects for every chemical, on a case-by-case basis. Consideration should be given to the quality and completeness of the data and the number and spread of the dose levels used. Besides the derived NOEL, all further information obtained in the long-term animal toxicity studies is valuable for characterizing toxic effects and determining safety factors. The type of toxic effect and the shape of the dose–response curve should also be taken into account in setting the size of the safety factor.

Also important are considerations of the ability to extrapolate from toxic effects seen in animals to human exposure scenarios and the results of human epidemiology studies, when available. Because of the complexity of information required, no universally accepted guidelines can be developed for determination of the precise magnitude of safety factors; therefore, expert judgment on an individual basis is a major factor contributing to the size of safety factors.

The safety factor approach has several problems. In experiments to determine the NOEL in animals, the experimental group size and the spacing of dose levels are major determinants of the numerical value of the NOEL obtained; the smaller the size of the individual dose groups and the larger the spacing of doses, the less likely is it that an effect will be observed. This phenomenon has the effect of rewarding poor experimental design because small group sizes in experiments will tend to produce higher NOELs. Moreover, nonthreshold effects may not be detected due to the low number of animals enrolled or the dose levels applied. In addition, the slope of the dose-response curve is often not considered or may not be determined with sufficient accuracy, and chemicals with steep and shallow dose–response curves are treated alike. Advantages and disadvantages of safety factors in the risk assessment process follow:

•Advantages
- Simple application
- Ease of understanding
- Flexibility of use
- Use of expert judgment

•Disadvantages
- Uncertainties of threshold values and size of safety factor
- No risk comparison possible
- Slope of dose–response curve not adequately considered
- Experimental NOELs are dependent on group size in the animal toxicity testing and end point selected

One of the most promising alternatives to the use of NOAELs or NOELs is the benchmark concept [194]. In the benchmark approach, a dose–response curve is fitted to the complete experimental data for each effect parameter. On the basis of the fitted curve, the lower confidence limit of the dose at which a predefined critical effect size is observed (i.e., the dose at which adverse effects start to arise or where 5% of the animals are predicted to be affected, effective dose, or ED_{05}) is defined as the benchmark dose. Advantages of this approach over the NOAEL are:
- The benchmark dose is derived by using all experimental data and gives a better reflection of the dose–response curve.
- The benchmark dose is independent of predefined dose levels and spacing of dose levels.
- The benchmark approach makes more reasonable use of sample size, and better study designs result in higher benchmark doses.

A disadvantage of this method is the uncertainty with respect to the reliability of the approach when results are obtained from toxicity studies performed according to the requirements defined in current guidelines. For the derivation of reliable dose–response relationships, the classical study design of three dose groups and a vehicle control group is limited, since adverse effects may only be observed at the highest dose level. An improved benchmark model fit could be achieved by increasing the number of dose groups without changing the total number of animals in the test.

At present, the determination of a NOAEL is mandatory for risk assessment in the EU. Nevertheless, the benchmark dose method can be used in parallel when a NOAEL cannot be established for the selected toxicological end point because only a LOAEL is available. In this case, benchmark modeling preferred over LOAEL–NOAEL extrapolation, which uses more or less arbitrary assessment factors. Benchmark dose software (BMDS) is available from the US EPA internet site (www.epa.gov).

5.2.4.2. *Risk Estimation Techniques for Nonthreshold Effects*

The procedures outlined below are most often applied to the low-dose risk estimation of human or animal carcinogens. Since dose–response data are not available for effects in animals at doses relevant to human exposure, extrapolations are required for determining the potential human cancer risk. The methodology employs mathematical modeling to characterize the relationship between exposure and response or to place an upper bound on the dose–response relationship. Dose–response data, available from specific study situations (mainly animal bioassays using high doses of the chemical and, sometimes, heavily exposed population groups), are extrapolated to the often much lower exposures of the general population in order to calculate the possible risk. Therefore, cancer risk assessment generally involves extrapolating risk from the relatively high exposure levels employed in animal studies, or occupational studies where cancer responses can be measured, to risks at the relatively low exposure levels that are of environmental concern. However, since the majority of carcinogenicity experiments use only two or three doses, it is impossible to assess the shape of the dose-response with a reasonable degree of precision. Risk assessment must therefore rely on some arbitrary assumptions about the shape of the dose-response relationship at low doses. Risk estimates thus obtained are not true or actual risk but values obtained by extrapolation well below the range of experimental observations. A summary of the advantages and disadvantages of quantitative risk assessment follows:

•Advantages
- Gives numerical values on risk that may be used for setting exposure limits.
- Permits the comparison of risks due to different chemicals.
- Provides a reasonable basis for setting exposure limits by identifying compounds with high risk.

•Disadvantages
- Extrapolation of data obtained at high doses to low doses relevant for human exposure by means of mathematical models which are not based on cancer biology and pathophysiology.
- Mechanistic and kinetic data are not used for the risk estimation process.
- Expensive and time- consuming lifelong bioassays are required.

The risk extrapolation techniques used are based on several conservative default assumptions, some unsupported by any direct empirical evidence. Conservatism is introduced to ensure maximum protection for those exposed to presumed chemical carcinogens. These assumptions were adopted to achieve some consistency in the application of risk-estimating techniques. The major assumptions are (1) carcinogenic risks are estimated from the data obtained in the most sensitive animal model only using positive responses (data from bioassays that do not show a treatment-related increase in cancer incidence are ignored); (2) linear, nonthreshold dose-risk models are applied; (3) statistical upper confidence limits are used rather than best estimates; and (4) a linear dose–response curve is assumed at low doses.

5.2.4.3. *Mathematical Models Used in High- to Low-Dose Risk Extrapolation*

Mathematical models for quantifying human cancer risk from exposure to carcinogens were first developed in the 1950s. These models were based on the one-hit or the multistage model of chemical carcinogenesis. A probit model was proposed in 1961 for assessing low-dose risk by extrapolation. An improved probit model was introduced in the 1970s by the FDA for computing the level of carcinogenic chemicals permissible in food. This procedure included the suggestion that the dose causing a very low risk (one additional cancer in 1 000 000 exposed people) to be considered as a “virtually safe dose.” Introduction of this mathematical model into

the risk assessment process stimulated the development of a variety of other mathematical models for carcinogen risk assessment. The basis of all the above methods is to apply a mathematical model to the tumor incidence observed in a long-term animal bioassay.

A major problem in dose– response and risk extrapolation is the determination of an appropriate mathematical model to predict effects at hypothetical low levels of exposure. Several models have been developed, and most of them contain analytical functions that appear to fit the experimental dose range quite well and also contain a dose–response functionality. Most models differ in the functions used to estimate response in the very low dose range (i.e., as dose approaches zero). The mathematical models in common use in carcinogen risk assessment are

- The linear model.
- Statistical or distribution models: log–probit, Mantel–Bryan, logit, Weibull.
- Mechanistic models: one-hit (linear), multihit, multistage (Armitage–Doll), linearized multistage, Moolgavkar model.
- Other models: statisticopharmacokinetic, time-to-tumor.

Linear Model. Linear extrapolation involves the intersection of a straight line between the origin (zero dose) and the upper confidence limit of the response at the single, lowest experimental dose. This model is based on the assumption that the increase in tumor incidence by the applied xenobiotic augments an already proceeding process.

Distribution models are based on mathematical functions of presumed population characteristics i.e. on the assumption that every member of a population has a critical dosage (threshold) below which the individual will not respond to the exposure in question. The probit model assumes that log dose–responses have a normal distribution. This model serves as the basis for the Mantel-Bryan risk extrapolation procedure. Other distribution models on which carcinogenicity dose–response models have been based include the logit and Weibull models.

Mechanistic models are based on the currently presumed mechanisms of chemical carcinogenesis. Each model reflects the assumption that a tumor originates from a single cell. The concept underlying the one-hit model is that a tumor can be induced by exposure of DNA to a single molecule of a carcinogen. This model is essentially equivalent to assuming that the dose–response is linear in the low-dose region and as a consequence tends to produce very low calculated “virtually safe doses” compared with the other currently applied models. The multihit model is a generalized version of the one-hit model which assumes that more than one hit is required at the cellular level to initiate carcinogenesis.

The biological justification for the multistage (Armitage–Doll) model is that cancer is assumed to be a multistage process that can be approximated by a series of multiplicative linear functions. It assumes that the effect of a chemical carcinogen occurs in multiple steps and that the effect of each step is additive. The dose–response predicted by this model is approximately linear at low doses and it results in estimates of potential risk that are similar to those of the one-hit model.

The Moolgavkar–Venson–Knudson model attempts a more comprehensive consideration of the biologic processes of cancer formation than the other mechanistic models and may provide a more accurate estimate of human risk by reducing some of the interspecies uncertainty. It is based on a two-stage growth model and considers the birth and death of cells, the effect of cell proliferation on the number of available cells for malignant transformation, and assumes two specific, irreversible, and rate-limiting mutational events to be necessary for cancer development. This model may quantitatively consider major phenomena influencing cancer formation such as cell proliferation, initiation/promotion, genetic predisposition, and synergism/antagonism. Moreover, model parameters may be obtained experimentally. At present, the major limitation for the application of this model is the lack of availability of many of the important biological parameters.

Other Models. The carcinogenicity of many chemicals is based on their biotransformation to reactive metabolites. The statisticopharmacokinetic model arises from consideration of competing metabolic activation and deactivation processes (e.g., detoxification and DNA repair) and estimates the “effective dose”, i.e., the level of reactive metabolites formed and interacting with critical macromeolecules, rather than the administered dose.

A modification of the Probit model relates it to the time at which a tumor is detected. For risk assessement, this time-to-tumor model uses the time to observance (latency) in addition to the proportion of animals bearing tumors at each dose.

5.2.4.4. *Interpretation of Data from Chronic Animal Bioassays*

The results of experimental animal studies may provide a variety of data in addition to the simple indication of the presence or absence of cancer. This information may be useful for the evaluation of potential human cancer risk and includes the number of neoplasms per animal, the number of different types of neoplasms observed, and the number of species affected. The organ or target tissue in which the carcinogenic response occurs is also important, as some rodents have extremely high and variable spontaneous incidence of certain tumor types. Where a chemical increases the number or accelerates the formation of neoplasms which spontaneously occur in high and variable incidence, the response carries less weight than the appearance of tumors with very low spontaneous rates. The time to development of tumor will also give an indication of potency. Further considerations on the interpretation of the obtained data are given in Section Bioassays to Determine the Carcinogenicity of Chemicals in Rodents.

5.2.4.5. *Problems and Uncertainties in Risk Assessment*

The practice of using tumor incidences obtained in long-term animal experiments with high doses (MTD, maximum tolerated dose, see Section Bioassays to Determine the Carcinogenicity of Chemicals in Rodents) for human cancer risk assessment and several of the conservative default assumptions used in the extrapolation processes have become the subject of major criticism. Some of the assumptions made when using experimental animal data for human risk assessment are not directly testable experimentally. Nevertheless, these assumptions are widely used because risk assessment would be difficult or impossible without them [188].

However, recent results on the mechanisms of carcinogenesis have revealed a complex biological process with many variables; a comprehensive consideration of all these parameters by a single, generally applicable mathematical model is not possible. Moreover, observations such as nonlinear toxicokinetics and delineated mechanisms of action for nongenotoxic carcinogens have indicated that a more scientifically based approach to carcinogen risk assessment, likely in a case-by- case examination by expert panels, may be more appropriate for defining actual risk than mathematical modeling. The major points of controversy in risk extrapolation from animal experiments and possible solutions to reduce uncertainties are described in Table 41.

Table 41. Uncertainties in quantitative risk assessment and the application of scientifically based methods for reduction of these uncertainties

Uncertainty	Reduction by
Extrapolation between species	physiologically based toxicokinetic modeling, comparative studies on toxicokinetics
Extrapolation from high to low dose	toxicokinetic modeling, quantitative determination of dose – response for biochemical effects of xenobiotics (e.g., DNA adducts, genetic changes), mechanisms of carcinogenesis
Extrapolation from controlled experimental conditions to variable human situations	none
Conservatism	elucidation of mechanism of actions
Toxicity and increased cell proliferation	dose – response for cell proliferation and cytotoxic effects
Dosimetry	toxicokinetic modeling and physiologically based toxicokinetic modeling
Mixtures	research on mechanisms of interactions
Bioassay-inherent factors in risk assessment	expert judgment

Extrapolation Between Species. In the absence of information on the possible mechanism of carcinogenesis by a particular xenobiotic, the tumor incidences observed in an animal experiment are often assumed to be useful in assessing human risk. However, the differences in the physiology and anatomy of laboratory animals and humans are well recognized. For example, the life span of the laboratory rodent is approximately two years whereas that of humans is approximately seventy years. Cancer appears to develop in rodents over a time scale that is proportional to the life span, and it is generally assumed that this will apply to all chemicals being assessed. The assumption that humans will respond in a similar fashion to laboratory animals is frequently shown to be inappropriate. Mechanistic studies demonstrate that qualitative and quantitative aspects of toxicokinetics and biotransformation, DNA repair and tissue susceptibility, and immune and other defense mechanisms may explain observed differences in the response of laboratory species and humans to exposure to carcinogens [195]. Expert judgement may be required to assess the nature of the end point or the mechanisms of carcinogenic action of the chemical in the experimental animal and to decide whether they are

relevant to man.

Extrapolation from High to Low Dose. The use of very high doses in animal cancer bioassays and the required extrapolation form high to low dose are a major point of critisim. Most cancer bioassays are performed in relatively small groups of rodents (between 50 and 100) and with administration of high doses. The highest dose selected is usually the “maximum tolerated dose” (MTD) in order to have maximum sensitivity and to ensure that the results obtained do not overlook a carcinogenic response simply because the dose was too low.

The following information that is obtained in bioassays with high doses in animals:

- Definite identification of compounds with carcinogenic activity in the species.
- Information about relative potency of different chemicals.
- Information about the carcinogenic activity of the test chemical, when administered alone.
- Characterization of tumor types, target organs, and presence or absence of dose–response relationship, which permit comparison of different chemicals and help in establishing structure–activity relationships to improve predictive capabilities.
- Information on the lack of carcinogenicity of many chemicals to assist priority setting in public health.

However, they also have the following limitations:

- No direct information about effects at doses lower than dose studied.
- No information on the mechanism of carcinogenicity.
- No information on the effects of the test compound, when administered together with other chemicals (synergistic/antagonistic effects).
- Use of high doses that may cause unspecific toxic effects contributing to carcinogenicity.
- Acute toxic effects that may prohibit long-term administration of specific chemicals in sufficiently high doses to cause tumors.

Human exposure to carcinogens usually occurs at doses several orders of magnitude lower than those used in the experiment. Clearly, the possible shape of the dose–response relationship is vitally important in establishing the likely effects at doses substantially below those in the observable range. Mathematical models used for extrapolation only give the upper limits of risk, the real risk may be somewhere between zero and the number calculated. Since the dose–response relationship can not be determined experimentally, application of different mathematical models results in markedly different slopes of the curves in the low-dose range (Fig. 69), and this has major implications for risk assessment and the establishment of ADI values.

Figure 69. Possible slopes of dose – response curves in the very low dose range below the ability of experimental determination in cancer bioassays

• = Experimental data point

Only one study to determine the actual shape of the dose–response curve at low doses with group sizes large enough to constitute statistical significance was performed, the so-called ED_{01} study using the potent carcinogen 2-acetylaminofluoren as a model compound administered in the diet to mice. Urinary bladder and liver neoplasms were found to be related to 2-acetylaminofluorene administration. The resulting tumor incidences showed that even within one species and with one specific carcinogen, there are major differences in the shape of the dose–response curve at low doses taht depend on the target organ affected. The incidence of bladder tumors at all time points suggested the presence of a threshold for this end point, whereas the dose–response data for the liver tumors was nearly linear at all time points and did not indicate a threshold (Fig. 70).

Figure 70. Dose – response data for the induction of liver (Δ) and urinary bladder (•) tumors induced by 2-acetylaminofluorene in mice after 24-month administration in diet

Extrapolation from Controlled Experimental Conditions to Variable Human Situations. In most animals studies, all critical factors are carefully controlled to guarantee the reproducibility of experimental observations. This is in contrast to the sometimes very large differences and time-dependent changes in the environmental exposure and other circumstances of the human population, which cannot be simulated in animal experiments. The complexity of these circumstances (i.e., changing life-style factors or workplaces) would necessitate an assessment of each human individually. Thus, risk assessment normally extrapolates directly from the animal data unless good evidence exists to suggest that an important confounding factor has been introduced. Besides the variable exposure situations, the human populations exposed to chemicals often differ in age, sex, and ethnic background and will certainly have a more heterogeneous genetic makeup than experimental animals. For the majority of carcinogenic risk assessments, individual variability can be taken into account only by the application of safety factors to compensate for these uncertainties.

Dosimetry. The problems of estimating environmental and/or occupational exposure to potential carcinogens have been described above. There are equally difficult problems in extrapolating the doses applied in animal experiments to those which might be encountered by humans due to environmental or occupational exposure and to distinguish between administered dose and effective dose.

Doses can be extrapolated from animal experiments to humans by five methods:

1. Expression of dose as a function of body weight (mg/kg or mmol/kg).
2. Expression of dose as a concentration in food or water (usually parts per million, i.e., µg/g or µL/L).
3. Expression of dose as a concentration in inhaled air (usually parts per million, i.e., µL/L).
4. Correction of dose for surface area. This is achieved in a complicated process by first raising the body weight of the laboratory animal to the power of 2/3 or 3/4. The correction converts doses that are expressed as concentrations in air or food to milligrams per kilogram of body weight in the laboratory species. The dose is then corrected for body surface area and converted back to concentrations in air or food by using appropriate conversion factors for humans. Corrections using surface area are based on the observation that metabolic rate is proportional to body surface area. For acute toxicity, this method may have some merit, but the rate of biotransformation may differently affect the potency of a carcinogen, depending on the role of biotransformation in detoxification or activation. Using correction factors for surface area provides data suggesting that humans may be more susceptible to potential carcinogens than laboratory animals compared to the data obtained by extrapolation on the basis of body weight.
5. Extrapolation assuming that the tissue dose is the primary determinant of carcinogenic response. This approach requires a study of the pathways of biotransformation and the kinetics of the pathway that generates the ultimate electrophile. In vitro studies may be necessary to obtain appropriate human data.

Further problems occur if the experiment is carried out by a protocol that is completely dissimilar from the human experience, for example, if animal exposure is carried out for a lifetime and human exposure is for a shorter period or if the animal experiment uses an exposure route that is not relevant for humans. As a general rule for chemical carcinogens, where the target tissue dose is presumably the most important determinant of the carcinogenic potency, the total body burden must be computed from the various routes of exposure to assess overall dose.

Mixtures. Cancer bioassays in animals are most often performed with a single chemical of definite high purity; exposure of experimental animals to other chemicals or other confounding factors such as vector-based disease is carefully avoided. In contrast, humans are continuously exposed to mixtures of chemicals and other agents. Thus, even when animals or humans are exposed to two or more chemicals, further complications of data interpretation are introduced. In general, the response of the animal and the human will depend on whether the chemicals' activities are interactive or not and whether the effects of the chemicals are similar or not. If the chemicals are not interactive and the response is similar, an additive effect may be assumed to occur. If they are not interactive, the overall response may be less than additive. In addition, a variety of metabolic or infectious diseases in the course of a human's life may have major impact on the development of a certain tumor due to exposure to the chemical under question. It is not feasible to simulate these real-life factors in the experimental situation [196].

Bioassay-Inherent Factors in Risk Assessment. A variety of biological factors exist that influence the assessment of carcinogenic hazard. Among these are the quality of the experiment, including the quality of the pathology, environmental control of animal facilities, estimation and standardization of chemical administration, purity of the chemical administered, and many other factors that together make up compliance with good laboratory practice. A further problem may be encountered if differences occur in outcome from different experiments. In the majority of cases, some aspect of an exceptional experiment may explain why the response was different (e.g., use of a different strain of animal). Since only positive data are used and negative data are ignored for carcinogenic risk assessment purpose to provide a conservative estimate of risk, this factor may also contribute to an overestimation of risk.

Conservatism and the Mechanisms of Chemical Carcinogenesis. To provide maximum protection, a conservative approach to risk assessment is preferred. This approach assumes that a single molecule of a carcinogen can interact with DNA and produce cancer; therefore, there can be no threshold for chemical carcinogenesis. Moreover, selection of the most sensitive response, irrespective of mechanism of action, and the assumption that the dose–response is linear at low doses may overestimate risk. This overestimation may be due to the unknown degree of conservatism at each step and to the amplification of previous bias in the assumption by the next step. The magnitude of overstatement of risk by these conservative assumptions is unknown, but is claimed to amount to several orders of magnitude.

Role of Toxicity and Increased Cell Proliferation. Critics point out that the high doses used in rodent carcinogenicity studies may have nonspecific effects such as an increase in the rate of cell proliferation due to cytotoxic effects [197]. These effects can be unique to high doses, and mitogenesis may itself be mutagenic in numerous ways, either by errors in replication or by conversion of endogenous DNA damage (e.g., by oxidative processes) and exogenous DNA damage to mutations before repair can occur. Moreover, sustained increases in the rate of cell proliferation may also yield secondary mutational events and could be important in the promotional phase of carcinogenicity by increasing the clonal expansion of initiated cells and thus increasing the chance that multiple critical mutational events will occur [198]. Thus, cell division will increase the chance of tumor formation. In this case, the tumor incidence for the same chemical applied at much lower doses is likely to be much lower than a linear model would predict and may even be zero [165, 199, 200]. Therefore, it would be important to add methods for determining cell division to animal cancer bioassays and apply the obtained results to estimate low-dose risks more adequately. Cell proliferation has been implicated as a major contributor to the cancerogenicity of several chemicals such as phenobarbital, 1,4-dichlorobenzene, *d*-limonene, and peroxisome proliferators.

Selection of Mathematical Model. The various models used in risk extrapolation fit the experimentally observed data well; however, they predict widely differing potential risks at low doses. Depending on the data used in the calculation, the predicted risks may differ by several orders of magnitude. These differences are inherent in the application of mathematical models, since only two or three doses are used in the experimental dose groups.

5.3. Future Contributions of Scientifically Based Procedures to Risk Assessment and Qualitative Risk Assessment for Carcinogens

Since quantitative cancer risk assessment can neither claim to be a scientific basis for development of historical models nor attempt to incorporate the large amount of scientific data on the mechanism of carcinogenesis into the assessment of risk, qualitative approaches considering all relevant data may be the best available solution for risk assessment. This approach, referred to a “weight-of-evidence determination of risk” is increasingly emphasized by regulatory authorities. The weight-of-evidence approach includes critical evaluation of the animal bioassay and all other available information on adverse effects of the chemical together with biotransformation, toxicokinetics, and expert judgment [201].

The criticims outlined above have demonstrated the need for further refinement of the extrapolation procedures by toxicokinetics and studies on the mechanisms of tumor formation. The role of animal experiments in predicting the potential risk of human carcinogen exposure will likely remain an important step of the risk assessement process despite the obvious limitations of this approach [197, 202]. However, the data obtained with animals must be interpreted with caution and in light of other data, both quantitative and qualitative, on the adverse effects of the compound (Table 42).

Table 42. Descriptive dimensions proposed as a framework to facilitate the use of mechanistic data in evaluation of carcinogenic risk to humans

Data set	Example of information required
Evidence of genotoxicity	DNA adduct formation, mutagenicity, bioactivation
Evidence of effects on the expression of genes relevant to the process of carcinogenesis	alterations of the structure or quantity of product of a proto-oncogene or suppressor gene
Evidence for effects on cell behavior	mitogenesis, cell proliferation, hyperplasia
Evidence of time and dose – response relationships and interactions	initiation, promotion, progression

Application of Toxicokinetic Models in Risk Assessment. Information on the way in which a chemical is absorbed, biotransformed, and excreted may be critical in extrapolating the relevance of the results obtained in experimental animals to humans [130, 203]. For the purposes of risk extrapolation, it is generally assumed that the administered dose is proportional to the effective dose. However, many chemicals are known to be carcinogenic only after they have been activated to reactive electrophiles by enzymatic reactions. The amount of reactive metabolite formed might not be directly related to dose because saturable enzymatic processes are involved in both bioactivation and detoxication. The extent of bioactivation and detoxication may therefore be highly dose dependent, and the relationship between administered dose and target dose may not be linear at all administered doses. For example, when high-affinity, low-capacity enzymes catalyze the detoxication of a xenobiotic and low-affinity, high-capacity enzyme catalyze its bioactivation, the amount of reactive metabolite formed is likely highly dependent on the administered dose (i.e., a tenfold higher administered dose may result in a 100-fold higher effective target dose). Moreover, there may be depletion of cosubstrates required by the enzymes catalyzing bioactivation or detoxication. After the reactive metabolite is formed, it is often deactivated by a second enzyme, such as epoxide hydrolase or glutathione *S*-transferase. These enzymes can also be saturated. The reactive metabolites that are not destroyed by these detoxication pathways may bind to DNA. The metabolites bound to DNA can be removed by saturable DNA repair systems. These effects are referred to as nonlinear toxicokinetics. Nonlinear kinetics are also seen with chemicals inhibiting or inducing drug-metabolizing enzymes. Application of a carcinogen at high doses may result in the induction of enzymes catalyzing its bioactivation and may leave detoxifying enzymes unaffected. Thus, the expected steady-state concentrations of reactive intermediates present in the cell and capable of binding to DNA are expected to be disproportionately higher after application of high doses which induce biotransformation enzymes than after low doses which leave the levels of biotransformation enzymes unaffected. Moreover, the metabolism of a xenobiotic may be changed as a consequence of the effects of long-term administration of the chemical [204].

To estimate the dose-dependent relationship between administered dose and the effective dose, toxicokinetic models incorporating saturable processes have been applied. The examples in Figure 71 show the theoretically derived relationships between administered dose and effective dose for the same chemical in animals by varying the kinetic parameters for bioactivation, detoxication, and DNA repair [205]: saturation of enzymatic bioactivation (A), saturation of detoxication and activation (B), and saturation of activation, detoxication, and DNA repair (C).

Figure 71. Possible relationships between administered dose and effective dose for the same data set including correction for nonlinear toxicokinetics

A) Saturation of enzymatic bioactivation; B) Saturation of detoxification and activation; C) Saturation of activation, detoxification, and DNA repair

The shapes of the curves in the low-dose range are shown in detail in the small sections.

The hockey-stick shape of the dose-response curve may remain unnoticed in animal experiments with high dose. The nonlinear correlation between effective dose and administered dose in the low, relevant dose region for human exposure may result in a decrease in the potential risk of exposure when compared to risk estimation based on experiments with high doses. Effective doses may be determined by measuring the amount of DNA adducts formed after administration of a carcinogen based on the assumption that for genotoxic agents the carcinogenic response is related to the extent of DNA adduct formation in target tissues. Unfortunately, nonlinear dose–response curves for effective doses have not yet been observed experimentally; all attempts to determine the dose-dependent formation of DNA adducts of potent carcinogens have shown linear relationships between administered dose and effect [206]. However, the increased sensitivity of analytical instruments currently available offers the opportunity to study the dose–effect curve for a wide range of carcinogens transformed to intermediates with different electrophilic reactivity in the low-dose range by quantifying the dose-dependent concentrations of DNA lesions. Quantitation of xenobiotic–hemoglobin adducts and chromosomal abnormalities in lymphocytes (e.g., siste-chromatid exchange frequency) offers other examples of biological markers that may prove useful in the definition of dose–response curves. The application of these procedures offers the advantage of obtaining quantitative information on a nonstochastic effect thought to be relevant in the mechanisms of carcinogenesis and thus in risk assessment.

As noted in Section Problems and Uncertainties in Risk Assessment, dosimetry may be a major cause of uncertainties in risk extrapolation form animals to humans. Besides saturable enzymatic reactions, the effective dose of a carcinogenic chemical may also be influenced by species differences in absorption, distribution and elimination, which may also be influenced by the dose administered.

To account for such factors, physiologically based pharmacokinetic models are increasingly used in the process of risk assessment. The principal purpose of the application of physiologically based pharmacokinetic models is to predict the concentration of carcinogen at the target site and describe the relationship between administered dose and target dose over a range of concentrations. By application of these models, a more accurate dose extrapolation is possible over broad ranges and may also incorporate nonlinearities in bioactivation and detoxification. Since the principles employed in the development of these models apply across species, the definition of the relationship between administered dose and effective dose and the important rate processes that cause a deviation from linearity permits a more accurate species extrapolation. The application of known physiological parameters may also enable the prediction of target organ concentrations in humans when direct measurements are not possible and may permit the comparison of different routes of application for effective dose. Physiologically based pharmacokinetic models are increasingly used to support quantitative risk assessments. Due to the risk estimates based on effective dose rather than external dose levels and the consideration of potential nonlinear relationships, an overestimation of risk obtained by linear extrapolations may be overcome and result in more scientifically founded risk assessments.

Mechanisms of Carcinogenicity and the Risk Assessment Process. Research on the molecular effects of particular agents has increased our understanding of the mechanisms of carcinogenicity. A range of biological processes has been implicated in carcinogenesis. Some of these mechanisms may be common to most carcinogens, others may be restricted to particular classes of chemicals or specific circumstances. In spite of the incomplete knowledge on carcinogenesis and a limited understanding of many processes, mechanism.based decisions are increasingly being introduced into risk assessment [207].

The emerging field of molecular toxicology may hold promise for the future of human risk assessment, and the application of methods developed for molecular biology may also offer more accurate ways of assessing human risk. The most promising application of mechanistic results for risk assessment are non-genotoxic carcinogens [208]. A number of xenobiotics are carcinogenic in animals but do not cause any detectable mutagenicity in in vitro studies. In contrast to other chemical carcinogens, which affect multiple organs or both sexes of both rat and mouse, many nongenotoxic carcinogens affect only a single organ in a single sex of a single species [133]. There are numerous examples of xenobiotics or treatment regimens in which production of tumors in animal experiments unlikely involves interaction of the xenobiotic or its metabolite with DNA. Examples include the induction of subcutaneous sarcomas by the repeated injection of glucose or saline solutions, the induction of skin cancer after chronic skin damage, and the induction of bladder cancer by the implantation of solid materials [209]. Recent experimental evidence also suggests that a number of xenobiotics that do not damage DNA may induce cancer in specific organs after systemic administration. Examples include chemicals binding to the circulating protein α_{2u}-globulin [210], peroxisome proliferators, and several structurally unrelated compounds interacting with receptors [211] (Table 43).

Table 43. Examples of nongenotoxic carcinogens and Their presumed mechanisms of action

Class of nongenotoxic carcinogen	Typical examples	Presumed mechanism of action
Peroxisome proliferators	diethylhexylphthalate	receptor-mediated increase in gene transcription, oxidative stress
α_{2u}-Globulin-binding agents	unleaded gasoline, limonene, decalin	regenerative cell proliferation due to cytotoxicity
Phenobarbital		mitogenic activity
Chlorinated dioxins	2,3,7,8-tetrachlorodibenzodioxin	receptor-mediated increase in gene transcription
Hormones	17- α-ethynylestradiol	receptor-mediated increase in gene transcription

The terms “genotoxic” and “nongenotoxic” were defined by Butterworth [133]: “A genotoxic agent is one for which a primary biological activity of the chemical or a metabolite is alteration of the information encoded in the DNA. These can be point mutations, insertions, deletions or changes in chromosome structure or number. Chemicals exhibiting such activity can usually be identified by assays that measure reactivity with the DNA, induction of mutations, induction of DNA repair or cytogenetic effects. Nongenotoxic chemicals are those that lack genotoxicity as a primary biological activity. While these agents may yield genotoxic events as a secondary result of other induced toxicity, such as forced cellular growth, their primary action does not involve reactivity with the DNA.”

Xenobiotics such as unleaded gasoline, limonene, and 1,4-dichlorobenzene induce renal cancer in male rats, but not in female rats or in either sex of mice [212]. Metabolites of these xenobiotics bind to the circulating protein α_{2u}-globulin, whose synthesis in the rat is under the control of androgens. The modified α_{2u}-globulin is concentrated in the kidney proximal tubules and is not degradable by the processes responsible for degradation of unmodified α_{2u}-globulin. Thus, accumulation of the modified protein causes cytotoxicity and regenerative cell proliferation, which has been implicated as the cause of tumor formation in the kidney.

Tumors in organs whose function is regulated by the endocrine system are often observed after hormonal therapies in humans and hormone treatment in animals and, due to the absence of genotoxicity of most hormones, nongenotoxic processes involving receptor-mediated transcription and activation or repression of specific genes have been implicated in hormonal carcinogenesis [213].

For both of the above cited examples, threshold mechanisms may be postulated. Kidney cancer induced by α_{2u}-globulin-binding agents requires cytotoxicity and cell death. Nontoxic low concentrations of these xenobiotics applied may not be tumorigenic. For receptor-mediated processes, a disproportional relationship between receptor occupancy and hormonally mediated cancer is also considered likely [214-216]. Hence, any assessment of carcinogenic risk of these chemicals must take into account the mechanisms by which they produce their effects.

The use of molecular toxicology in risk assessment is also advocated by the International Agency for Research on Cancer [207]. A monograph on the identification of cancer risks by mechanistic investigations suggested that cancer risks by mechanistic investigations suggests that “when available data on mechanisms are thought to be relevant to evaluation of the carcinogenic risk of an agent to humans, they should be used in making the overall evaluation, together with the combined evidence for animal and/or human carcinogenicity.” The consensus report further states that no definite guidelines for the inclusion of mechanistic data in the evaluation of carcinogens can be elaborated. However, a range of options are available: “First, information concerning mechanisms of action may confirm a particular level of carcinogen classification as indicated on the basis of epidemiological and/or animal carcinogenicity data. Second, for a particular agent, strong evidence for a mechanism of action that is relevant to carcinogenicity in humans could justify ‘upgrading’ its overall evaluation. Third, an overall evaluation of human cancer hazard on the basis of animal carcinogenicity data could be downgraded by strong evidence that the mechanism responsible for tumor growth in experimental animals is not relevant to humans. In keeping with the goal of public health, priority must be given to the demonstration that the mechanism is irrelevant to humans.”

5.4. Risk Assessment for Teratogens

The timing of exposure and patterns of dose–response from animal studies have important implications for extrapolating animal data to humans. A wide spectrum of end points can be produced, even under the controlled conditions of timing and exposure that can be achieved in animal studies. In some cases, the spectrum includes a continuum of responses, with depressed birth weight or functional impairment occurring at low doses, birth defects at intermediate doses, and lethality at high doses. Less commonly, birth defects alone or lethality alone are produced. Therefore, in estimating human risk, all exposure-specific adverse outcomes must be taken into consideration, and not just birth defects.

A similar response pattern is observed in humans exposed to developmental toxicants. The spectrum of responses is determined by the time and duration of exposure, magnitude of exposure, and interindividual differences in sensitivity. Hence, manifestations of developmental toxicity can not be expected to be identical across species; that is, an animal model can not be expected to forecast exactly the human response to a given exposure. For instance, an agent that induces cleft palate in the mouse may elevate the frequency of spontaneous abortion or retard growth in humans. However, any manifestation of exposure-related developmental toxicity in animal studies can be regarded as indicative of a spectrum of response in humans.

Epidemiological data suggest that the majority of human embryos with chromosomal and/or morphologic abnormalities are lost through early miscarriage and that relatively few survive to term. Consequently, determination of malformations or growth retardation at the time of birth alone (malformations, stillbirths, low birth weight) is likely to result in a substantial underestimate of the true risk, since the onset of embryolethality would be missed.

The sensitivity (ability to detect a true positive response in humans) and specificity (ability to detect a true negative response in humans) of laboratory animal studies have been evaluated [217]. Of 38 compounds with demonstrated or suspected teratogenic activity in humans, all but one (tobramycin, which causes otological

deficits in humans) tested positive in at least one animal species. Approximately 80% of the compounds were positive in multiple species. A positive response was elicited to 85% in the mouse, 80% in the rat, 60% in the rabbit, 45% in the hamster, and 30% in the monkey. These findings indicate that the usual laboratory animal species are highly sensitive for detecting human teratogens.

In contrast to the high sensitivity, laboratory animals show low specificity for predicting human teratogenesis; of 165 test compounds with no evidence of teratogenic activity in humans 65 (41%) were positive in more than one animal species. The high percentage of false positive results (i.e., compounds with no evidence for human teratogenicity inducing malformations in animals may be in part accounted for by the high doses usually applied in the animal tests. Also, human studies determine effects from the time of birth onward, which may result in underestimation of the true risk.

[Top of Page]

Abbreviations:

Ah-R: arylhydrocarbon receptor

AP: apurinic/apyrimidinic site

APS: adenosine 5′-phosphosulfate

BHK: baby hamster kidney

BIBRA: British Industrial Biological Research Association

CoA: Coenzym A

DDT: 1,1′-(2,2,2-trichloroethylidene)bis-(4-chlorobenzene)

DHHS: U.S. Department of Health and Human Services

DHP: delayed hypersensitive response

ECETOC: European Chemical Industry Ecology and Toxicology Centre

ED: effective dose

ELISA: enzyme-linked immunosorbent assay

FCA: Freund's complete adjuvant

FAD: flavine adenine dinucleotide

GABA: ϒ-aminobutyrate

GC/MS: gas chromatography/mass spectroscopy

GOT: glutamic acid oxalacetic transaminase

GSH: glutathione

GSSG: glutathione disulfide

GST: glutathione *S*-transferase

GTP: guanosine 5′-triophosphate

HGPRT: hypoxanthine – guanine phosphoribosyltransferase

IPCS: International Programme on Chemical Safety

LDH: lactate dehydrogenase

LOAEL: lowest-observed-adverse-effect level

LOEL: lowest-observed-effect level

MIF: migration inhibition factor

mRNA: messenger RNA

MTD: maximum tolerated dose

NADPH: nicotinamide dinucleotide phosphate (H)

NOEL: no-observed-effect-level

NTP: National Toxicology Program

PAPS: 3′-phosphoadenosine-5′-phosphosulfate

PG: prostaglandin

rRNA: ribosomal RNA

SHE: Syrian hamster embryo

SMART: somatic mutation and recombination test

T, or TCDD: 2,3,7,8-tetrachlorodibenzodioxin

TD: tumor dose

TK: thymidine kinase

tRNA: transfer RNA

UDP: uridine diphosphate

UDPG: uridine diphosphate glucose

UDPGA: uridine diphosphate glucuronic acid

UDS: unscheduled DNA synthesis

1. Industrial Chemistry and Law

1.1. Law, Society, Chemistry, and Ethics

Law is the normative instrument that society uses to determine in a peaceful way the rules governing the relations between people (private law); people and authorities (public law); and states (international public law). It reflects to a large extent the values and ethics of a given society at a given time (→ Sustainability and the Chemical Industry – Ethical Aspects and Approaches). Normative activities have – at an early stage – addressed the question of humans and their interface with industrial and trade activities either to promote such activities, to control or restrict them, or in some cases, even to prohibit them.

Although the requirements of an organized society, as reflected in law, are supposed to be integrated, complementary, and consistent, they might actually conflict or at least appear contradictory. For example, the legal system might aim at economic objectives – for example, the free movement of products in an economic area – as reflected in one of the four basic freedoms of the European Communities Treaties. On the other hand, society and lawmakers might impose severe restrictions on the movement of products because of their impact on organized collectivities and the environment (see Section 4.3).

Law might actually impose restrictions and administrative burdens on research, production, transport, and distribution activities, either because of the "dangerous" nature of such activities or because they involve products that are, to various degrees, considered dangerous or simply perceived as negative or hostile to people or the environment. The end of the twentieth century has seen the emergence of the "environmental society". With the growing satisfaction of basic needs in the developed world and the collapse of traditional ideologies, growing awareness of environmental problems has become a major factor influencing sociology, politics, law, and economics. In parallel to the new "environmental" awareness, and in apparent contrast, industry and trade activities are more and more characterized by increased competition and "globalization." After the success of the General Agreement on Tariffs and Trade (GATT) round in Uruguay and the creation of a World Trade Organization, the dominant economic concepts and trade realities are clearly hostile to trade barriers and restrictions. The resolution of potential and actual conflicts between these two approaches should lie in a coherent and humanistic vision, based on human values, on responsibility, and on confidence in sustainable progress and science.

The main objective of this chapter is to focus on a few key trends which affect, or will influence, the socio-legal framework in which industry has to operate. As shown in the various chapters of the keyword Legal Aspects, innovation, production, distribution, and marketing strategies must integrate environmental and other ethical values which determine their legal framework.

At the same time, industry's response should be based on sound and credible science, on economic sense and on appropriate communication.

In other words, modern *legal systems* tend to address production, distribution activities and products from "cradle to grave" and respond to a growing social concern about perceived risks

generated by "dangerous" activities and products. This is particularly relevant in the area of chemicals which are subject to comprehensive sets of rules in the various regions of the world (see Chaps. 3, 6, 7). Perceived risks may be real and have to be seriously addressed. They may also result from fears generated by some media or pressure groups. In contrast, *science* has never been more advanced but, in a way, has become a victim of its own success as technology allows society to better measure even minor risk factors (or simply traces) which are then deemed to be unacceptable. [See for example the progress of detection limits of modern analytics using ultrasensitive equipment and the debate on the revision of the Drinking Water Directive [1]. The key issues are the allowance of greater flexibility for nonhealth parameters and reliance on toxicological data in setting maximum admissible concentrations (MAC) for health-related parameters. Progress in toxicological, analytical, and epidemiological knowledge and methods may imply that MAC should evolve, in line with WHO guidelines.]

The importance of innovation as a driving force of modern economy and society was defined by SCHUMPETER at the beginning of the 20th century as the entire process from the birth of an idea through to its widespread application in society. Innovation implies changed technologies, economic and social evolutions, and adaptability. The driving forces of innovation and changes are rooted in human curiosity and needs and are influenced by their evolving hierarchy.

Social psychology based on MASLOW's approach, distinguishes five hierarchical levels of needs

1) Physical survival and physiological needs
2) Safety
3) Social belonging
4) Respect and recognition
5) Self-fulfilment

According to classical marketing sciences, innovation was responding to "technology pushes" on the one hand and almost unlimited "market demands" on the other hand. Until the lower needs are satisfaction of human needs as described in MASLOW's ladder in industrialized countries and with the achievement of high standards of living, perceived priorities have evolved. Public awareness has become more and more attentive, and critical of "side effects" of innovation.

In other words, the better and the more social needs are fulfilled, the more acute is the perception and concern of the society about the instruments developed to respond to such needs and about their effects. This phenomenon has had a direct and massive impact on the lawmaking process and has led to a vast number of regulations, particularly in the health, safety, and environment area.

The Rio United Nations Conference on Environment and Development (UNCED) Declaration is probably the widest international effort to address environmental concerns on a global basis, although reflecting different Regional sensitivities and priorities. The growing environmental awareness has generated many "law – regulatory"-driven technologies and market developments (e.g., the compulsory introduction of catalytic converters for automobiles) and has led to the phased withdrawal of products considered as harmful to the environment (as for example, the phasing out of CFCs, initiated by the 1987 Montreal protocol on substances that deplete the ozone layer). Market and competition effects are far-reaching.

In the face of these developments and in parallel to the international, European and national lawmaking process, industry has gradually developed comprehensive "pro-active" programs. Such programs are meant to meet the public's and the authorities' concerns and to offer a sound managerial and operational response from industry. Such a response may take the form of general policy declarations or more operational programs. [See for example the "Business Charter for Sustainable Development" (November 1990) of the International Chamber of Commerce. The Charter lists sixteen principles for Environmental Management.] Typically, one leading feature of such policies is the improvement of information flows between industry, the public and the authorities.

On a more sectorial basis, the "Responsible Care" program developed by the chemical industry on a worldwide and a Regional basis reflects this sector's commitment towards achieving continuous and measurable progress in the health, safety, and environment areas. Association members of the International Coun-

cil of Chemical Associations, such as the European Chemical Industry Council (CEFIC), the Japanese Chemical Industry Association (JCIA), and the U.S. Chemical Manufacturers Association (MA) have identified Responsible Care as a priority and a contribution to sustainable development.

1.2. Policy and Legal Principles Affecting Industrial Chemistry

Years have seen the emergence of two major policy principles that influence and will continue to impact with special significance the lawmaking process affecting the exercise of activities related to chemicals.

1.2.1. Precautionary Principle

The "precautionary principle" has been used more and more frequently and quoted in public statements adopted in several international forums and according to some opinions has become a principle of (customary) international law [2–5]. Examples of international forums include:

1) Bergen Conference on Action for a Common Future, Norway, May 8 – 16, 1990. The Bergen Conference was organized by the government of Norway in cooperation with the UN Economic Commission for Europe as part of the preparation of the UN Rio Conference on Environment and Development. The Bergen Conference established that "in order to achieve sustainable developments, policies must be based on the Precautionary Principle. Environmental measures attack the causes of environmental degradation."
2) Principle 15 of Rio Declaration on Environment and Development, Rio de Janeiro, Brazil, June 13, 1992. "In order to protect the environment, the precautionary approach shall be widely applied by States according to their capabilities. When there are threats of serious or irreversible damage, lack of full scientific certainty shall not be used as a reason for postponing cost-effective measures to prevent environment degradation."

The precautionary principle is part of the wider concept of sustainable development and has been integrated in the European Communities' law since its introduction in the Maastricht Treaty [6]. Article 130 r, § 2, of the Treaty explicitly refers to the precautionary principle: "Community policy on the environment shall aim at a high level of protection . . . . It shall be based on the 'Precautionary Principle' and on the principles that preventive action should be taken, that environmental damage should as a priority be rectified at source and that the polluter should pay . . . ."

The new European Constitution is a major example of the fast recognition in a legally binding instrument of the two major principles for future environmental policies.

The precautionary principle institutionalizes caution when (sufficient) evidence exists that an activity or substance is likely to cause unacceptable harm to the environment. Its actual meaning, interpretation, and definition, however, are much debated because the implications of the principle could be far reaching, if not devastating. Definitions vary widely from encouraging a cautious and responsible attitude, based on scientific evidence, not to generate or discharge in an uncontrolled way elements hostile to humans and the environment, to a much more radical "anti-industrialization" attitude, which is leading to the prohibition of substances or activities even in the absence of conclusive scientific evidence. According to the precautionary principle, as defined by part of the doctrine and in several marine pollution conventions, a substance of activity posing a threat to humans or to the environment should therefore be prohibited (i.e., banned or restricted) even if there is no conclusive scientific proof of a causal link between that particular substance, or activity, and humans or environmental damage.

This rather radical approach was first used in the Ministerial Declaration of the Second North Sea Conference [7]. "The Parties agree to . . . accept the principle of safeguarding the marine ecosystem of the North Sea by reducing polluting emissions of substances that are persistent, toxic and liable to bioaccumulate at source by the use of the best available technology and other appropriate measures."

This applies especially when there is reason to assume that certain damage or harmful effects

on the living resources of the sea are likely to be caused by such substances, even where there is no scientific evidence to prove a causal link between emissions and effects ("the principle of precautionary action").

The overall goal was to achieve a substantial reduction in the total quantity of persistent, toxic and bioaccumulative substances reaching the North Sea. Actual policies of Member States are aiming at a target of 50 %. The national interpretations of the London Declaration have been far from homogeneous, most of them requiring some certainty of (scientific) evidence regarding environmentally damaging effects (i.e., France) or calling for actual evidence before taking action.

Those variations clearly reflect the embarrassment of public authorities who are confronted by complex situations in which multiple causation factors make scientific assessment and conclusions difficult or uncertain. [This embarrassment was reflected in the Third International Conference on the Protection of the North Sea, The Hague, March 7 – 8, 1990 (Third North Sea Conference). The final declaration confirmed the continuous application of the precautionary principle but limited it to those substances that are persistent, toxic, and liable to bioaccumulate.] A radical interpretation of the precautionary principle as reflected in the London Declaration is seriously objectionable – from both legal and scientific standpoints – because it conceptually opposes and rejects scientific evidence and causality as instruments for sound policy actions.

Such an interpretation necessarily leads, at the extreme, to an impasse and might be translated into a "paralysis principle." Indeed, a requirement based on the existence of "reasons to believe" that damage or harmful effects are "likely" to be caused becomes meaningless if opposed to or separated from scientific evidence. For example, a mere trace of a substance in the environment would equal pollution of that environment leading to possible prohibitons. The progress of analytical methods today allows the detection of minute quantities of a given substance (e.g., a piece of sugar in a lake). The progress of scientific and analytical methods without parallel progress of impact and risk assessment techniques could actually multiply purely "emotionally"-based policies. The exclusion of scientific evidence as a determining factor for shaping environmental policy might actually lead to the opposite of a precautionary and reasonable attitude. At the extreme, it might lead to decision-making processes entirely dominated by "beliefs" and "opinions" dominated by ideology without due regard for an objective and scientifically sound analysis of facts.

The radical interpretation of the precautionary principle seems to be disregarded by provisions of Article 130 r of the Maastricht Treaty. While endorsing the concept of the precautionary principle, the Treaty does not define it and obliges the Community to take account of available scientific and technical data [Article 130 r (§ 3)].

Realistically, complex situations and interactive systems might lead to a degree of uncertainty where scientific evidence is incomplete or even appears contradictory. The lack of full scientific evidence might encourage policy makers to take measures "where there are threats of serious or irreversible damage." Such measures must, however, be based on sufficient scientific evidence.

It remains to be seen if and how a moderate and reasoned interpretation will finally emerge in the international and national spheres, where scientific evidence and causation will actually serve and precondition the applicability of the precautionary principle.

[A dramatic and illustrative evolution has been the apparent change of policy of the U.S. administration, which, under the Reagan and Bush presidencies, carefully avoided endorsing the principle, while the EPA, under President Clinton, developed a strategy that would prohibit, reduce, or substitute the use of chlorine and chlorinated compounds on the basis of such a principle.

Clean Water Initiative Submitted to Congress, 1 February 1994. While aiming at a strategy for prohibiting, reducing, and substituting the use of chlorine and chlorinated compounds, the administration proposed a time schedule allowing federal agencies and "other experts" to comprehensively assess the use the environmental and health impacts of chlorine and chlorinated compounds, and availability and relative efficiency and safety of substitutes. Within 30 months, a plan "for our appropriate actions" should be developed. The National Academy of Sciences is expected to complete a

study for the Congress on the current knowledge of chemicals "that exhibit endocrine immune and nervous system health effects in human and wild life." The highly political and emotion-driven nature of this issue is demonstrated by the more moderate approach of the administration, which resulted from fierce reactions from many circles, including industry.]

The sole answer for policy makers is to develop more, not less, science and technology assessment and to assist policy and decision makers to take the most appropriate decisions.

1.2.2. The Polluter-Pays Principle

Historically, an economic and preventive principle, the "polluter-pays principle" is gradually influencing public and administrative law, or civil law.

The polluter-pays principle was initially adopted by the OECD in its Recommendations [8]. The 1991 OECD Recommendation [9] extended the polluter-pays principle to the "cost of damage" generated by pollution.

The Parliamentary Assembly of the Council of Europe summarized the extension of the polluter-pays principle to compensation of damage as follows:
"States, industry and all persons shall be liable to pay for the environmentally harmful consequences of their actions and development programmes ... The principle of the polluter's liability, or the "Polluter Pays Principle" as it is commonly known, shall be strictly applicable." [Recommendation 1130 (1990)]

The polluter-pays principle has been introduced into the European Communities Constitution via Article 130 r of the Single European Act [10] and later in the Treaty on the European Union. The extension of the polluter-pays principle as an environmental law principle has received priority consideration by the OECD. In its preventive form, the principle implies that those whose emissions could create a risk to the environment should bear the full cost of reducing or eliminating such emissions so as to prevent this risk from materializing.

The principle is thus also a means of internalizing environmental costs [11]. However, it is not yet clear what impact it will have in specific areas such as civil liability for damage, although it may be argued that it is based on a similar concept, i.e., the author of a damage, to persons or to property, has to compensate for such damage.

One of the important, and complex, questions raised by the polluter-pays principle within civil liability mechanisms is linked to the very question of "what is a damage?" since there is a tendency to extend the notion of damage to "damage to the environment", or "ecological damage". These are extremely difficult to define and to quantify. (For example, how is the degradation of the ozone layer to be evaluated in terms of damage and to which cause can it be rationally attributed? Who is the polluter? The "global climatic change" issue raises a number of complex questions of this nature.)

Other difficulties are linked to the establishment of causation, when several sources of pollution exist, and to the establishment of evidence. Should the plaintiff bring the full evidence that damage was caused by a given attributable incident?

Or is "prima facie" evidence sufficient? Should the burden of the proof be reversed with the risk of jeopardizing the very concept of civil liability? These, and other questions, have been debated in the context of the "Council of Europe" Convention and are still much argued within the European Union.

Efforts have also been made to make civil liability rules not only a legal instrument for compensation of injury to people and damage to property but also to use them as a (limited) tool for environment remediation. It is sometimes argued that strict civil liability could play a role in the prevention of environmental degradation and therefore be used as an instrument of environmental policy.

1.3. Economic Integration and Environmental Protection

The interface between economic integration and environmental protection is a major emerging issue at the end of the 20th century. Both on the world trade scene and within the European Union, law and policymakers have to reconcile potential conflicts between the logic of economic integration implying and enforcing similar rules and policies to facilitate trade and competition and, on the other hand, the logic of na-

tional/regional prohibitions and restrictions on products and activities. Global issues call for global solutions. Achieving cohesion is far from obvious, as illustrated by the present debates concerning the tensions between the Internal Market of the Community and environmental policies, but also in the debate within the World Trade Organization.

International trade of products which might have an impact on the environment is increasingly subject to severe restriction and/or to authorization and information procedures. For example, the case of waste movement restrictions and free trade is illustrative of such tensions. The EC Regulation on Control of Waste of February 1, 1993 [12] is intended to implement the Basel Convention on the "Control of Transboundary Movements of Hazardous Waste and their Disposal" (adopted and opened for signature on March 22, 1989). This Regulation completes and tightens the monitoring system already applicable in the Community. It covers five categories of transport: transfer between Member States, transfer within Member States, export to non-EC countries, imports from outside the EC and waste transfers. The role of the OECD, in seeking a workable solution especially for waste for recovery should be stressed.

The Regulation provides for a prior authorization system, recognizes a broad right for Member States to object to shipment and implements the self-sufficiency and the proximity principles which both aim at encouraging local waste disposal. Paradoxically, a piece of Community legislation, supposed to have direct effects, is opposing one of the fundamental freedoms of the EC Treaty, i.e., free circulation of goods. This has raised much criticism within the Community and the legal debate continues on the (impossible?) reconciliation of free movement of goods principles and restrictions of transboundary shipments of waste and recyclable materials (secondary raw materials) (see Chap. 4). Rather than concentrating its policy on the proximity principle, which may actually create inefficiencies and additional unnecessary costs, the Community should develop sound and uniform criteria for operating waste facilities and movements of waste.

Another example of restrictions to trade motivated by environmental concerns is the prior informed consent (PIC) procedure. The PIC procedure is based on the principle that international shipment of a chemical that is banned or severely restricted in order to protect human health and the environment should not proceed without the agreement, or contrary to the decision of, the designated national authority in the importing country [13–17]. These developments raise the question of their interface and compatibility with world trade liberalization agreements under the GATT. There is no doubt that the whole "trade and environment" debate will constitute a major global policy issue of the end of this century. For a comprehensive review, see [18].

1.4. Other General Trends of Health, Safety and Environmental Laws Affecting Industrial Chemistry

While legislations dealing with environmental aspects of industrial activities have to be situated within general public and civil law, the evolution of health, safety and, especially, environmental (HSE) laws has been characterized by the following elements:

1) A more autonomous, systematic system of law is gradually developing both in the national, European, and international spheres. The fast development of a European Community comprehensive environmental law is based on policy programs which aim at fully integrating environmental policies in other Community policies and in setting long-term objectives and targets [19], [20]. The primacy of Community law over national legislation, where sufficient, clear, and precise provisions exist, and the direct effect into national legal systems have far-reaching implications.
2) The gradual emergence of a "right to know" both in the European Union and in the United States is a good example of the impact of environmental law concepts on public and administrative law. This right to know gives citizens broad access to information obtained by public authorities in the environmental area, subject to some limitations [21].
3) The impact of environmental issues on competition policy. In a growing number of cases, "environmental benefits" are claimed in industrial and marketing strategies both

vis-à-vis consumers and vis-à-vis public authorities. This development raises many questions about ethics and (fair) competition. The eco-label concept is an illustration of this evolution [22].

Other aspects are linked to state aids given for environmental purposes which might distort competition in a given industrial sector.

The European Commission has issued guidelines describing its policy on state aid for environmental protection. Such guidelines would authorize up to 30 % state subsidy for (voluntary) investment related to the environment, while investment aimed at compliance with environmental legislation could be supported up to 15 % of the cost [23].

1.5. Scope of this Keyword

The keyword Legal Aspects does not aim at providing a comprehensive or exhaustive review of European, national, or international rules affecting chemicals. For a publication relating to international aspects of chemical control see [24]. The mere coverage of, for example, European Community legislation would require several volumes of Ullmann's. Many specific aspects have already been addressed in other keywords dealt with in volumes B 7/B 8 or in relevant sections of them. The main objective of the keyword Legal Aspects is to make better understood the interface between the legal system in general and chemical-related activities and to present in this respect the major trends characterizing the evolution of law on the eve of the year 2000.

2. European Community Legislation Affecting Chemicals

Definition of Terms Used in this Chapter. The European Union (EU) was set up by the Treaty of Maastricht, which came into force in November 1993. Part of the Treaty on the EU are the Treaties on the European Communities (EC), the EURATOM Treaty, and the Coal and Steel Treaty.

The EU does not have legal personality, but the EC has. Therefore, any legal instrument is adopted not by the EU but by the EC. Whenever references to legal texts are made, the term EC is correct, EU may only be used in a political context.

Prior to the coming into force of the Maastricht Treaty the correct name for the EC was European Economic Community (EEC). Thus, all legal texts adopted before November 1993 have in their title the reference EEC.

2.1. The European Community Framework

The European Community has, under different Treaties, the objective of creating an integrated economic community in which industrial frontiers are no longer economic frontiers, and which includes the free circulation of goods and services, capital, and labor as well as a high level of health, safety and environmental protection. The mandate to establish and monitor the Internal Market for goods and services, capital, and labor is in the Treaties given to Community institutions: Council and Commission, the European Parliament, the Economic and Social Committee, and the European Court of Justice (ECJ). Member States have the objective of facilitating achievement of the Community's tasks, and abstaining from any measures that could jeopardize the attainment of Community objectives [25]. In contrast to that there is the joint responsibility between the European Community and its Member States acting in isolation to ensure an appropriate protection of the environment [26]. This principle of subsidiarity, enshrined since autumn 1993 in the general provisions of the EC Treaty, has existed since the 1987 amendment of the environmental chapter of the EEC Treaty. Proposals for legislation made by the EC Commission have been adopted or rejected without express recurrence to this principle.

Chemical legislation in the European Community must find its way through this framework of responsibilities. In very broad terms, past legislation on product standards was generated mainly at Community level and thus had a considerable degree of uniformity. Legislation banning products or restricting their use was more often adopted at a national level; with the completion of the internal Community market, a marked trend exists towards integrated rules

for bans and restrictions, but progress is slow. With regard to production-orientated legislation, Community legislation in the past has been unsystematic and limited to framework rules. The tendency has developed to arrive at a more systematic approach, although the responsibility for rule making remains shared between Member States and the Community, the Community being limited to umbrella legislation.

2.2. Product-Oriented Legislation

Community legislation on chemical substances and preparations as well as on specific chemical products – food additives, pharmaceuticals, cosmetics, fertilizers – started early in the 1960s, shortly after the creation of the EEC. This legislation was based almost entirely on Article 100 of the EEC Treaty, which reads:
"The Council shall, acting unanimously on a proposal from the Commission, issue Directives for the approximation of such provisions laid down by law, Regulations or administrative action in Member States which directly affect the establishment or functioning of the common market. . .".

Total or Optional Harmonization? The approximation of national legislation aimed at diminishing the differences between national rules that created, or were capable of creating, barriers to the free circulation of goods. Since in all the above-mentioned sectors of chemical products, questions of health and safety considerably influenced rule setting, the EEC did not attempt the legislative technique called "optional harmonization" but rather used a "total harmonization" approach.

Under *optional harmonization*, Member States fix standards for national production at their discretion and at a level they consider appropriate. However, they are obliged to admit on their market those products from other Member States that comply with Community standards. This kind of approach was, for instance, largely used by the EEC in the area of technical legislation.

Under the *total harmonization* approach, which was used in the area of chemical products, national legislation is replaced by Community legislation so that, finally, one rule exists within the Community. This approach is obviously more ambitious, more delicate, and more time consuming. Since questions of health and safety are central to all Member States' national policy, progress in replacing the different national rules by one single Community rule has been slow and even slower in the areas of food and pharmaceuticals than in other areas.

In the area of chemical substances and preparations, national legislation in the 1960s was not very sophisticated. Therefore, attempts to create uniform rules for chemicals were relatively successful. Community legislation on chemical substances [27], solvents [28], pesticides [29], and paints and varnishes [30] was adopted soon after the transition period for setting up the EEC. This legislation set uniform rules for the classification, labeling, and packaging of substances and preparations, and ensured that chemicals conforming to these requirements were allowed to be circulated freely within the Community. Since this legislation in the 1960s and 1970s had to be adopted unanimously, Member States were able to block the adoption of Community legislation that did not conform to their national rules on health and safety, until their concern was met.

A Dynamic Cooperative System under the Control of the Commission. The possibility of blocking legislation served to protect the interests of Member States in terms of health and safety, before such legislation was adopted. However, this need could also arise after the adoption of Community legislation, for instancce, when an accident in a Member State demonstrated that the Community rule was not strict enough or where new scientific evidence was found. Since an amendment of Community legislation was slow and required an initiative from the EEC Commission, this mechanism was not considered able to adequately cover all cases. Therefore, the Community legislation on chemicals contained a safety clause: where a Member State found that a chemical, although complying fully with Community rules, presented a risk to health and safety, the Member State was allowed to take provisional measures to counteract that risk. These measures could even go so far as to remove the chemical from the market. The Member State that took such a measure had to inform the Commission and other Member

States of its action and give a reason for its decision. Then, a Community procedure was started to decide whether the national measure should be extended to the entire Community. Until such a decision, the national safeguard measure was maintained. By way of illustration, the text of such a safeguard clause is given here [31]:

"Where a Member State has detailed evidence that a substance, although satisfying the requirements of this Directive, constitutes a hazard for man or the environment by reason of its classification, packaging and labelling, it may provisionally prohibit the sale of that substance or subject it to special conditions in its territory. It shall immediately inform the Commission and the other Member States of such action and give reasons for its decision. The Commission shall consult the Member States concerned within six weeks, then give its view without delay and take the appropriate measures. If the Commission considers that technical adaptations to this Directive are necessary, such adaptations shall be adopted, either by the Commission or by the Council in accordance with the procedure laid down in Article 21; in such a case, the Member State which has adopted safeguard measures may maintain them until the adaptations enter into force."

In the mid-1970s, two elements were added to this situation – attempts to introduce Community-wide bans and restrictions on chemicals, and rising environmental concerns. Clearly, the feeling was that legislation on chemicals that tried to open up national frontiers and set uniform rules was insufficient since national prohibitions and restrictions for use continued to exist, and with growing concerns for health, safety, and the environment, new restrictions were being introduced at the national level. To ensure uniform standards, the EC felt the need to adopt Community-wide restrictions or bans. This legislation [32] was adopted on an ad hoc basis: whenever nationally – or indeed in international bodies – the need was felt to ban or restrict the use of a chemical product, the European Economic Community tried where appropriate, to reach Community-wide standards. The difficulty of reaching a consensus on such restrictions under the unanimity rule had, as a consequence, the adoption of a relatively limited number of such Community rules. Several attempts to accelerate the decision-making procedure at the Community level were unsuccessful, probably mainly because Member States were reluctant to see responsibility for health and safety questions shift more and more to the Community. Thus, between 1976 and 1992 some 30 substances were banned or severely restricted in use, covering only a part of the national bans or restrictions.

The second element was upcoming environmental concern in legislation. This concern gradually led some Member States to legislate in the area of chemicals, in order to protect, preserve, or improve the quality of the environment. The EEC reacted by including environmental considerations into its existing legislation on chemicals. The evolution of Directive 67/548/EEC, adopted in 1967 at Community level, is characteristic in this regard: in the mid-1970s, France informed the Commission of its intention to introduce new chemical legislation that took into a account environmental considerations. The Commission was of the opinion that such legislation would be capable of creating new obstacles to trade within the Community. Therefore, it suggested an amendment to Directive 67/548/EEC that finally led to the adoption of Directive 79/831/EEC, which, for the first time in such precise terms, talked of the need "to protect man and the environment" [33]. Since environmental policy is based, among other factors, on the principle that preventive action should be taken [34], that Directive introduced the principle that before new chemical substances were placed on the market, information had to be provided to competent authorities, together with test results on the substances, in order to enable the authorities to evaluate the foreseeable risk for humans and the environment. This evaluation is made Community-wide in concert between national and Community administrations. Conditions for marketing of new chemical substances based on health, safety, or environmental considerations are fixed for the entire Community.

A similar approach regarding notification prior to placing a substance on the market was used when the Community adopted legislation for genetically modified organisms on the market (deliberate release) [35]. Again, evaluation of the risk of such deliberate release is made Community-wide prior to the release.

However, this approach is by no means generalized; it is not applied to all chemicals, i.e., chemical preparations can be placed freely on the market without prior provision of test results and other information to competent authorities.

In 1987, the EC Treaty was amended. Specific rules were introduced to ensure achievement of the Internal Market by the end of 1992. For that purpose, a new Article 100 a provided that measures with the objective of achieving the Internal Market could be adopted by majority decision of Member States. At the same time, a new Article 100 a (4) was included in the Treaty, which reads:

"If, after the adoption of a harmonization measure by the Council acting by a qualified majority, a Member State deems it necessary to apply national provisions on grounds of major needs referred to in Article 36, or relating to protection of the environment or the working environment, it shall notify the Commission of these provisions. The Commission shall confirm the provisions involved after having verified that they are not a means of arbitrary discrimination or a disguised restriction on trade between Member States . . .".

Furthermore, Community environmental policy was considerably strengthened, by the introduction of an environmental chapter, Articles 130 r to 130 t, into the Treaty. Environmental measures were, in principle, to be adopted unanimously (Art. 130 s). Article 130 t stipulated, "The protective measures adopted in common pursuant to Article 130 s shall not prevent any Member State from maintaining or introducing more stringent measures compatible with this Treaty."

The borderline between the provisions of Article 100 a and Article 130 s seems, with regard to chemical products, to be rather clear: since chemical preparations are products and should –under the concept of an Internal Market, where national frontiers are no longer economical frontiers – circulate freely within the Community, the legal foundation for rules on their classification, labeling, or packaging – including their ban or restrictions on use – should be based on Article 100 a. Article 130 s would be reserved to production-related legislation that did not affect the establishment or the functioning of the Internal Market.

The majority of Community chemical legislation did indeed follow this approach. However, not all legislation respected this pattern. When the Council adopted legislation on chlorofluorocarbons (CFCs) and other ozone-depleting substances, this legislation was based on Article 130 s [36]; the same approach was followed on waste legislation, although, from the point of view of the environment, there exists little difference between poisoning by chemicals or by waste [37]. Thus, because of national initiatives remaining possible under Article 130 t, uniformity of rules within the Community was not achieved.

Even where new legislation on chemicals was based on Article 100 a, the establishment of uniform rules was questioned. Indeed, certain interpretations of the above-mentioned clause of Article 100 a (4) are equivalent to the wording of Article 130 t. In other words, this interpretation would allow Member States, after the adoption of Community standards, to introduce new, diverging rules at the national level, not merely to continue to apply national legislation that existed prior to the adoption of Community rules. Whether Article 100 a really has the same meaning as Article 130 t or should be interpreted more narrowly, remains to be decided by the European Court of Justice, which, until now, has not had occasion to pronounce itself on this question.

Pending this question and more generally, Member States remain responsible, together with Community institutions, for the protection of health, safety, and the environment. They have thus not lost the responsibility for banning or restricting the use of chemical products, as long as no comprehensive legislation setting up Community-wide bans and restrictions exists. Article 100 a, seen in more general context, enables the Community to draft uniform rules for chemicals that are based on a high level of protection of health, safety, and the environment. To the extent that the Community manages to elaborate, adopt, and permanently adapt such rules to technical and scientific progress, recurrence to national bans and restrictions will not be necessary; thus Article 100 a (4) would lose practical importance.

The Maastricht Treaty on European Union has not changed the principles on rule making at the Community level. Thus, the trends described

above are likely to remain applicable in the coming years.

2.3. Legislation on Chemical Installations

As stated above, Community legislation on chemical installations has not been very systematic in the past. The establishment and functioning of a common market were not in the past perceived to require the elaboration of Community-wide standards for industrial installations. Thus, rules affecting chemical installations were set up only with the introduction of an environmental policy at the Community level and under environmental protection auspices. Industrial installations that discharge dangerous substances into waters or into groundwater or emit pollutants into the air need specific authorization for such emission [38]. Such permitting rules were, however, far from covering all installations or all pollutants.

An industrial accident in Seveso, Italy, provoked Community legislation on the prevention of major accident hazards of certain industrial activities [39]. This so- called Seveso Directive, adopted in 1982 and amended several times, requested installations that process or stock chemicals to take measures to prevent industrial accidents, to inform the adjacent population of potential risks, and to elaborate on-site and off-site emergency plans. This legislation is described in detail in Chapter 5.

In 1985, the EEC adopted a Directive that required an environmental impact assessment for a number of public or private projects, before planning consent was given [40]. In 1993, the EEC adopted a Regulation on the voluntary participation in a system of eco-auditing [41]. This Regulation aims at the improvement of eco-management by industrial installations. The Regulation will take effect in spring 1995. Also, in 1993, the Commission proposed a legislative measure at the Community level on integrated pollution control, which aims at a generalized, integrated permitting system for industrial installations, in order to improve, rationalize, and harmonize authorizations for industry and adequately protect the environment [42].

These Community rules on chemical installations were either umbrella rules or left Member States relatively large discretion in complementary rule making at the national level. This reflects the fact that while chemical products should circulate freely within the EC, the chemical installations that produced these products are not movable. Therefore, where legislation on installations was adopted prior to the 1987 amendment of the EC Treaty, it was based on Articles 100 and 235 of the EC Treaty at the same time. After the single Act 1987 took effect, Community legislation on installations was based on Article 130 s; the one exception until now – legislation harmonizing national programs on disposal of waste from the titanium dioxide industry, which was finally based on Article 100 a of the EEC Treaty [43] – seems isolated. In general, legislation on industrial installations will for the foreseeable future probably be based on Article 130 s of the EEC Treaty. This is likely also to apply to accessory environmental legislation, such as emission of pollutants into the air or soil.

The consequence of the use of Article 130 s is that Member States, under Article 130 t, will remain entitled to maintain or introduce more protective legislation with regard to chemical installations. Different national legislation, however, might lead to different production costs and gradually influence the competitive situation of industrial installations. This, in turn, might have an influence on the free circulation of goods produced in such installations. Where Community rules on installations have a significant impact on the cost of production, good reasons exist to consider whether the establishment of an Internal Market does not require equivalent standards over the entire Community territory. This would suggest that for such rules, Article 100 a be chosen as a legal basis, since standards that are laid down on the basis of Article 130 s will – because of the existence of Article 130 t – never be capable of achieving uniformity. For example, Directive 82/501/EEC on the prevention of major accidents, which affects mainly industrial installations that produce or process chemical products, might well request such considerable investments for accident prevention that rules within different Member States would distort competition for the chemical products that are placed on the market. According to the content of such a revised Directive, good reason might thus exist to base such a Directive on Ar-

ticle 100 a and not on Article 130 s of the Treaty. Indeed, the precise content of the Directive will determine whether one can argue that the objective of such an accident prevention Directive was principally the protection of humans and the environment and whether the establishment of local competitive conditions among installations was only an accessory objective.

3. Towards the Adoption of New Civil Liability Rules: A New Challenge for the Chemical Industry

"Toutes les pertes et tous les dommages qui peuvent arriver par le fait de quelque personne, soit imprudence, légèreté, ignorance de ce que l'on doit savoir, ou autres fautes semblables, si légères qu'elles puissent être, doivent être réparées par celui dont l'imprudence ou autre faute y a donné lieu. Car c'est un tort qu'il a fait, quand même il n'aurait pas eu l'intention de nuire." Extract from "Lois Civiles, II" by Jean Domat (1625 – 1696). The original French text can be translated as follows: "All losses and all damage caused by the deeds of any person, through negligence, thoughtlessness, ignorance of what one should know or similar shortcomings, however trivial they may be, must be compensated by the person whose fault or negligence has created the damage. Because he generated a tort, even though this was unintentional."

3.1. Introduction

Significance of Civil Liability and its Evolution. A significant number of research, production, and processing activities are carried out by a host of individuals and companies. Once manufactured, the most diverse products – from the simplest to the most technologically complex – are put on the market and are subject, among other things, to transport, packaging, labeling, and storage operations. All of these activities may cause damage either to persons, to goods, or to the environment. Thus, one can easily imagine the importance of "civil liability law" or "third-party liability" and its economic impact on industry. "Manufacturer's liability" must be considered in the framework of general legal systems of third-party liability, or "responsabilité civile ou quasi-délictuelle" in French civil code systems.

Basics of Civil Liability. Traditionally speaking, civil liability for damage means an obligation, under certain conditions, to compensate for damage caused to persons, property, or proprietary rights. The concept of environmental damage is relatively new and refers only to the nature of the damage. It basically addresses damage to the unowned environment, for example, disappearance of a fish species in a river. The plaintiff has to prove the existence of the following factors: (1) that he/she has suffered damage to his/her person or property; (2) that the damage was caused by an offense of negligence by the defending party (i.e., was based on fault); and (3) that a causal link exists between the damage and the incident.

These fundamental principles of civil law are similar in most European countries but are subject to evolution as described below. Liability instruments of direct interest to industry have been drafted in relation to

1) Defective products
2) Transport of (hazardous) goods
3) Industrial activities

Chapter 3 addresses liability, and compensation questions, in the context of industrial and marketing or trade activities. In the following material, the major trends affecting the evolution of civil liability are outlined, and various major international legal instruments recently adopted or still under discussion in this area are reviewed.

3.2. General Trends and Debates Affecting Modern Civil Liability Systems

3.2.1. New Trends

When can a Person or Company Be Held Liable? In most European countries, existing civil liability laws are based on fault ("continental law systems") or on the "negligence concept" ("common law systems"). However, in some countries new laws with a "strict" liability regime as a basis for liability have been enacted or are under consideration. The strict liability regime usually applies to damage caused

by activities that are deemed especially dangerous, such as handling hazardous waste, dangerous substances, or nuclear energy. In other cases, the case law (theoretically based on the fault concept), has led to a similar result. Under common law, the "duty of care" has been considerably extended and case law developed in the direction of strict liability. Similarly, fault-based liability is interpreted by courts and jurisdictions in such a stringent manner that the difference between these regimes has shrunk. Even without such specific law, the case law of most countries has developed a strict liability regime for damage caused by dangerous activities, such as handling explosives or operating dangerous installations.

At European level, the Directive on defective products (see Section 3.3) is based on strict liability of producers for defective products put on the market. A similar trend toward strict liability has characterized international conventions in the context of land and maritime transport of dangerous goods [the so-called International Institute for the Unification of Private Law (UNIDROIT) convention, and the present "Hazardous Noxious Substances" (HNS) draft convention of the International Maritime Organization].

Caution is needed and "labels" can be misleading because a fault-based liability regime can actually be more severe for potentially liable parties than a well-defined strict liability system. Enormous conceptual and practical differences also exist between the so-called strict liability systems.

For example, little common ground exists between the "operator's liability" approach, which is the basis of the Council of Europe Convention (see Section 3.7), and the absolute "generator's liability," which was once proposed in the context of a draft protocol on liability for waste to the Basel Convention [44]. Both texts are supposed to be based on strict liability. The operator's liability approach focuses on actual responsibility of the person in control of certain activities and substances; the generator's liability approach merely indicates who should bear the damage consequences of products (here waste) whether this person is, or is not, in control. The generator can be held liable even for acts committed by third parties, professional or not.

Arguments in Defense. Certain arguments may be used to defend oneself. One cannot be held liable if one proves the existence of "force majeure" (i.e., the damage was caused by an act of war or hostilities or by a natural phenomenon of an exceptional, inevitable, and irresistible character). A similar defense is, for instance, a claim that the damage was caused by an intentional act by a third party or that the person who suffered the damage had by his own fault contributed to the damage.

Additionally, different laws contain defenses of a special nature typical of the area concerned. The state-of-the-art defense is one example of regulatory exclusion of liability. According to the Directive on defective products, producers are not held liable if they prove that the state of scientific and technical knowledge at the time they put the product into circulation was not such as to enable the existence of a defect to be discovered.

In the context of liability related to industrial activities, compliance with permits is taken into consideration although it does not lead to an absolute defense. Emissions within "tolerable levels under local circumstances" (Council of Europe Convention) also offer possible defenses depending on legislation or case laws.

The Emergence of the Polluter-Pays Principle in Civil Liability Law (see Section 1.2.2). The polluter-pays principle was introduced in the European Communities Constitution via Article 130 r of the Single European Act and later in the Treaty on the Economic Union. Scientific literature on the polluter-pays principle is considerable but in what concrete and practical manner it will be applied is still unclear because interpretations of questions such as "Who is the polluter?" still differ.

3.2.2. Recognition of Ecological Damage in International and Community Law of Civil Liability

One of the most significant aspects of the present debates and current work in the international sphere is the extension of the concept of damage (death, personal injury, damage to property) to ecological damage. This same ecological damage is defined in various ways, depending on the instruments analyzed. Some common features

can, however, be identified: (1) environmental damage concerns the community, not the individual; (2) environmental damage is difficult to quantify. For example, what is the value of a variety of flowers that has disappeared because of pollution? U.S. jurisdictions and legal professions have made considerable efforts to quantify the ecological damage. Another interesting source is the case law developed in connection with major maritime pollution cases (e.g., the Amoco Cadiz decision).

The European Commission Green Paper on Remedying Environmental Damage of 1993 (see Section 3.2) envisages (1) the harmonization of civil liability rules for environmental damage and (2) the possibility of remedying environmental damage not met by the application of civil liability principles. The Green Paper, being a discussion document only, does not propose any definition of environmental damage but refers to definitions contained in the Council of Europe Convention and in the amended proposal for a Council Directive for damage caused by waste. The fundamental importance of and difficulties related to the definition are emphasized.

The 1991 amended proposal for a Council Directive on civil liability for damage caused by waste (see Section 3.4) defines "impairment of the environment" as any significant physical, chemical or biological deterioration of the environment in so far as this is not considered to be damage within the meaning of "damage to property." "Damage" as such, in turn, is traditionally defined to mean death or physical injury and damage to property. The compensation obligation under the Directive would apply for both damage and impairment of the environment. The Council of Europe Convention refers to "loss or damage by impairment of the environment . . . [which] shall be limited to the costs of measures of reinstatement actually undertaken or to be undertaken." This definition includes the definition of the "CRTD Geneva Convention" of October 10, 1989 (see Section 3.5).

The word environment is itself defined very broadly in the Council of Europe Convention; it covers natural abiotic and biotic resources, such as air, water, soil, fauna, and flora, and the interaction among the same factors, assets making up the cultural heritage, and the characteristic aspects of the landscape. These last two elements of the definition illustrate the erosion of the traditional concept of damage, because it is now a matter of covering damage to collective property by civil liability mechanisms. Such damage is particularly difficult to quantify. The Commission, unlike the Council of Europe, has avoided giving a definition of the word environment as such in the mentioned proposal for the Directive on liability for waste.

3.2.3. International Harmonization in the Context of Liability for Dangerous Activities

Opinion is growing that civil liability rules should be addressed at the international level not only in relation to products and goods, but also in respect of industrial activities. International rules are said to be necessary because pollution is no respecter of national boundaries and Member States have been establishing different Regulations in this field that could distort competition and hamper the smooth operation of a single market. Protection of the environment is also one of the Community aims, equivalent to creation of the single market, as enshrined in the Treaty of Rome Articles 130 r – t.

This approach was much debated in the early 1990s. Although harmonization of civil laws is conceptually attractive from the point of view of the Internal Market, it is effectively desirable for industry only if it would simplify existing systems and if new international instruments do not simply add another layer of possible legal actions. Harmonization efforts are also seriously challenged by the existence of different procedural rules linked to national judicial systems.

The two most important efforts to introduce harmonization of liability for dangerous activities have been developed within the Council of Europe and the EEC. The Commission Green Paper on Remedying Environmental Damage envisages harmonization of (strict) civil liability rules for environmental damage, as well as the possibility of remedying environmental damage not met by the application of civil liability principles. The latter means creating compensation funds to be used when no liable party can be identified or in case of the insolvency of the liable party. Civil liability is also considered the domain of Community legislation because it is a legal principle closely linked to general Euro-

pean enviromental policy principles, such as the prevention of damage and the polluter pays.

Another important international document is the already-mentioned Council of Europe Convention on civil liability for damage resulting from activities dangerous to the environment. The convention was influenced by major pollution of the Rhine river by Sandoz that affected several countries. It is based on the belief that issues relating to civil liability and compensation for damage resulting from dangerous activities need to be addressed at the international level.

3.2.4. Actions and Requests by Organizations

The right to sue is normally given only to the party with a legal (i.e., direct and certain) interest in recovering compensation for injuries or for damage suffered to property. Where damage occurs to property that is not owned (i.e., environmental damage), no injured party with the right to bring legal action can be identified. At the European level the tendency is to grant such a right – although limited and under the control and at the discretion of the courts – to environmental associations. This right to protect the "public interest" normally rests with the public authorities that operate under public law and democratic institutions.

For example, according to Article 4(3) of the amended proposal for a Council Directive on civil liability for damage caused by waste, common interest groups or associations, which have as their objective the protection of nature and the environment, are given the right either to seek remedy or to join in legal proceedings that have already been brought. Also the Council of Europe Convention gives certain restricted rights to associations seeking to protect the environment; namely, the group may request of courts or jurisdictions (1) that an unlawful, dangerous activity, which poses a grave threat of damage to the environment be prohibited; (2) that the operator be ordered to take measures to prevent an incident or, after an incident, to prevent damage; or (3) that the operator be ordered to take measures of reinstatement. However, any party to the convention may reserve the right not to apply this provision.

3.2.5. Financial Security Schemes

Several proposals suggest compulsory insurance or other financial security schemes to cover the liability under various pieces of legislation. Article 11 of the amended proposal for a Council Directive on civil liability for damage caused by waste provides that the liability of the producer, who in the course of a commercial or industrial activity produces waste, and of the eliminator of waste, be covered by insurance or other financial security. The amended proposal for a Council Directive on the landfill of waste, in turn, contains an obligation on the operator of the landfill to have a financial guarantee or any other equivalent, whose purpose is to cover the estimated costs of the closure procedures and after-care operations of the landfill (Art. 17).

3.2.6. Essential Requirements

The trends described above represent a real evolution in fundamental civil liability rules. However, some of them are still quite flexible, and others imply more theoretical than practical changes compared to the existing situation. An example of this is the discussion of whether liability should be fault based or strict.

Nevertheless, some essential requirements exist for any legislation on civil liability, one of the most significant of which is maintaining the establishment of causation. It is of utmost importance to the entire system that the causal link between the incident and the damage suffered be shown by the plaintiff. Likewise, in the context of damage caused by industrial activities, causation must be proved to exist between the operator in charge of the activity and the incident that led to the damage.

3.3. Liability for Defective Products and European Community Law

3.3.1. Background and Legal Basis

The Directive on defective products was approved by the Council on July 25, 1985 [45]. European Community Member States had to implement the Directive by July 1988. In early

1994, most Member States had effectively introduced the Directive into their internal law. Only France and Spain had not yet enacted the Directive, which led the Commission to open legal proceedings in the European Court of Justice for the noncompliance of these two countries with their obligations under the EC Treaty.

The declared objective of approximation of the laws has been partially attained since the text allows Member States to introduce some variations to three specific provisions. Article 100 of the Treaty of Rome provides the legal basis for the Directive and lays down the following conditions:

1) Unanimous council decision, based on a proposal from the Commission
2) Compulsory consultation of the assembly (European Parliament) and the economic and social committee if there is a need to amend national laws. Both institutions were consulted and expressed their opinion.
3) Grounds for the Directive: According to indent one, the approximation of the laws of the Member States concerning the liability of producers for damage caused by the defectiveness of products is necessary because existing differences may distort competition, affect the free movement of goods within the Common Market, and lead to differing degrees of consumer protection.
4) Social – political justification: The preamble assumes that "liability without fault on the part of the producer is the sole means of adequately solving the problem, peculiar to our age of increasing technicality, of a fair apportionment of the risks inherent in modern technological productions."

The industry has challenged strict liability and expressed preference for liability regimes based on fault or negligence in accordance with traditional principles of the law of torts. This battle was lost for the chemical industry, however, when even Italy, once a strong opponent of strict liability, accepted this regime in the political compromise that led to the adoption of the Directive in 1985. Was this a real source of concern to industry and should strict liability a priori be perceived as hostile by industry? The answer very much depends on three interrelated factors:

1) The content of actual provisions of the Directive
2) The content of national laws implementing the Directive
3) Case law, including that of the EC Court of Justice, that could play an important role in clarifying ambiguities

As stressed in Chapter 5, more important than the "labels" or names used to qualify liability regimes are their specific features. Other elements are also important: the practice of the courts, the judicial organization and its cost, and the general attitude of the public toward the liability and compensation system. In this connection, the Directive, although far from perfect from the point of view of legal certainty, was probably a reasonable compromise acceptable to governments, industry, and consumers (although some would not share this view, both in consumer circles and in industry).

As shown below, the question of recognition of the state-of-the-art defense was an important aspect of the "package" finally adopted and illustrates quite well the conceptual tensions and arguments that prevailed during the European Commission and the Council of Ministers discussions.

3.3.2. Nature of the Liability Regime

Principle: No-fault Liability. The Directive provides for the following system: the injured party has to prove the damage, the defect of a product, and the causal relationship between the defect and the damage (Art. 4). Thus, negligence and fault are no longer relevant as sources of producer's liability. Suppression of the "fault" standard should ease the task of the victim. However, it should be stressed that the case law of most countries had already introduced a softening of the victim's position, for example, in reversing the burden of proof or in extending considerably the concept of fault or "negligence" of the producer. According to common law concepts, the duty of care is now very strict indeed, with the important exception of the state-of-the-art defense.

Lines of Defense and Exemptions from Liability (Art. 7 of the Directive). The producer

must prove that his/her is one of the cases of exemption provided for, namely,

1) That he/she did not put the product into circulation
2) That the defect did not exist when the product was put into circulation or that it came into being afterwards
3) That the product was neither manufactured for sale or any other form of distribution, nor manufactured or distributed by him/her in the course of his/her business
4) That the defect is due to compliance of the product with mandatory Regulations issued by the public authorities
5) State-of-the-art defense ("development risk", see Section 3.3.3)
6) In the case of a manufacturer of a component, that the defect is attributable to the design of the product in which the component has been fitted or to instructions given by the manufacturer of the product

This last point is very important and was stressed by the chemical industry. All sectors of the chemical industry should be fully aware of this defense. It will be more and more important to have clear agreements between purveyors and buyers about the purity and characteristics of component products.

3.3.3. The Three Options of the Directive

A fundamental question that had to be addressed by the authors of the Directive was the so- called harmonization question. Should the EEC Directive provide for strict harmonization ("maximum Directive") or should it create a "minimum system" allowing the Member States to establish different and additional standards, depending on their concepts of consumer protection? Real harmonization being one of the raisons d'être of this text was preferable. The EEC Member States delegations recognized that a maximum Directive would be the best solution from the Treaty of Rome point of view, but at the level of details, compromises became necessary and the maximum approach turned into a limited approximation of laws.

State-of-the-Art Defense. A highly important question is, should the manufacturer of a defective product be held liable if the state of scientific and technological development did not enable him to detect the existence of a defect at the time the product was put in circulation. The inclusion of development risks in the scope of liability was predicted to interfere with technological innovation. Until now, in the vast majority of Western legal systems, no party has had to accept the risk of the unknown and unforeseeable. As CEFIC wrote in a position paper addressed to the EEC Council:
"While it is perfectly understandable that a system of liability should oblige producers to take all possible precautions against any possible injury to the consumer, it seems totally unreasonable to require that these same producers be liable for the unknown, and for risks over which they have no control whatsoever. Injury caused by a defect in a product cannot be a source of liability if the defect was undetectable and unforeseen at the time of its being put into circulation because of the state of the art."

After long and difficult debates, the EC Council finally introduced in the Directive what is known as the state-of-the-art defense. Accordingly, the producer has the possibility of proving that the state of scientific and technical knowledge when the product was put into circulation was not such as to enable the existence of the defect to be discovered. This defense may therefore be introduced in the legislation of Member States and was effectively introduced in most national laws of implementation.

However, the Community regime allows individual Member States to maintain the liability of the producer for "development risk" if it already existed in their internal laws when the Directive was approved (i.e., July 1985). Only Germany was affected by this provision, because its Pharmaceutical Act did not allow producers to use the state-of-the-art defense.

The Community regime also allows Member States to introduce derogations to that principle in new legislation, although this possibility is tempered by a clause of Community "standstill" and the obligation to follow a specific procedure under the supervision of the Commission [Art. 15 (1) of the Directive]. The importance of recognizing a state-of-the art defense for sectors such as the chemical and related industries is clear if its impact on research and development is considered, which in certain sensitive

areas might otherwise be discouraged. Evidence already exists, especially in the United States, showing that the liability regime based on absolute liability and disregarding important factors such as the state of technology and the plaintiff's behavior has had adverse effects on new products.

In the United States, the impact of certain court cases based on "absolute producer liability" on insurance costs and the (non)availability of coverage has been tremendous. In the Federal Republic of Germany, the Pharmaceutical Law has not – thus far – generated similar experiences. However, nobody can predict what the consequences would be for the German pharmaceutical industry of a serious "developmental risk" case similar to the thalidomide affair. The compromise achieved in the Directive on the state-of-the-art defense seems to preserve a fair balance and efficiency.

Derogation in Respect of Financial Limitation of Liability. The Directive makes no provision for a Community system of financial ceilings to liability. It does, however, allow Member States to introduce on an individual basis a liability "ceiling" for personal injury, which may then not be less than 70×10^6 ECU (European Currency Units). The German and Belgian laws have, for example, introduced such ceilings.

The Commission has been instructed to submit a report to the Council ten years after the date of notification of the Directive (1995). Acting in the light of this report, the Council is to decide whether or not to cancel the option of introducing ceilings. As with the state-of-the-art issue, such a provision will mirror the Council's political embarrassment at the time of its adoption. The Council will, however, be free to decide to maintain the state-of-the-art and the ceilings option if a political majority so wishes.

Derogation in Respect of Agricultural Products. The Directive normally excludes agricultural products from its scope. However, Member States are authorized to include them within their laws and to apply the regime of the Directive.

3.3.4. Other important Aspects of the Directive

The Directive covers not only personal injury but damage to property (with a "lower threshold" of 500 ECU in the second stage). This provision has led to some divergent interpretations.

Definition of Producer. "Producer" is extensively defined in the Directive as

1) The manufacturer of a finished product
2) The producer of any raw material
3) The manufacturer of a component part
4) Any person who, by putting his name, trademark, or other distinguishing feature on the product, presents himself as its producer

Clearly, the concern of the Directive's drafters has been to avoid the possibility of an injured person finding himself in a situation for which no one is responsible. Hence, care is taken in defining the producer. So true is this that the Directive provides for treating the importer into the Community as a producer within the meaning of the Directive and, should it prove impossible to identify the actual producer, treating the supplier as the producer.

Product Defectiveness. For the purposes of the Directive, a product is defective not according to objective or material criteria but with reference to the "safety which a person is entitled to expect." Thus, § 6 of the recital states that defectiveness does not mean the product's lack of fitness for its intended use but the lack of safety that the public at large is entitled to expect. Such a reference creates difficulties of interpretation. In reality, it will be for the judge to assess. However, the Directive provides that all circumstances be taken into account in assessing the safety the product should provide.

Some of the criteria to be considered in assessing the safety of a product are: (1) the presentation of the product; (2) the use to which it could reasonably be expected to be put; and (3) the time when the product was put in circulation. Safety is to be assessed by taking into account the expected use of the product, its marketing, the information given and user instructions, and similar factors related to the product.

Conclusion. The new Community regime on liability for defective products contains both pros and cons and seems generally balanced. Despite imperfections and weaknesses, it genuinely contributes to the progressive establishment of similar legislations in Europe: one major weakness is that it leaves open the question of diverging procedural rules in the judicial systems of the Member States.

Another important question is the possible impact of other more recent Community legislation, i.e., the Product Safety Directive and the proposed Directive on Liability of Suppliers of Services on the Product Liability System.

The Product Safety Directive was adopted on June 29, 1992 and had to be implemented by the Member States in June 1994. The Directive was challenged on grounds of the Maastricht Treaty "subsidiarity" principle by the Federal Republic of Germany. A very wide and strict "general safety requirement" is introduced, although the Directive does not apply to sectors that are already subject to specific legislation. The Directive introduces a general obligation to market "safe products" only, which is not the same concept as a (non)defective product of the Product Liability Directive. Other provisions address the following issues:

1) Monitoring of products
2) Provision of information to consumers concerning possible risks involved in use of the products
3) Adoption of measures to ensure information of consumers
4) Ensuring uniform management of tests, checks, warnings, prohibitions, and market withdrawals

In practice, this legislation should be seen in relation to the already existing comprehensive laws on safety and should contribute to the highest safety standard for products marketed in the European Union.

The proposed Directive on the Liability of Suppliers of Services would make the supplier liable for damage to the health and physical integrity of persons or to property caused by a fault committed by the supplier. However, the proposal "revises the burden of proof" since the supplier would have to establish the absence of fault. The prospects of the Directive being adopted were not very good in 1994 because most Member States were reluctant to accept Community legislation in this area.

The practical impact of the new Community regime, particularly on insurance costs, has so far not been dramatic, but it is still uncertain and will depend on the content of national laws and their application by national courts under the control of the European Court of Justice.

3.4. Community-Proposed Directive on Liability for Waste

Implementation of the polluter-pays principle provides for consideration of the scope of civil liability to better define responsibility in the environmental field. So as to answer this requirement, also expressed in the previous Directive on the control of transfrontier movements of waste (84/631/EEC) and several other Community documents, the Commission in 1989 submitted a proposal for a Directive on civil liability for damage caused by waste. This proposal was amended two years later, in 1991 [46].

The proposal raised a number of arguments, one of them being that the Community Directive on civil liability should be compatible with the UNIDROIT Convention and, on a broader level, with the approach developed in the Council of Europe Convention. With the content of the amended proposal, this compatibility did not seem ensured. For example, contrary to the international conventions mentioned, the proposal channelled liability onto the waste producer regardless of whether or not the producer was in control of waste. To create a system that is workable and practicable, all other equivalent instruments must be studied and considered. Although the proposal was put aside pending the results of comprehensive discussions on the basis of the Green Paper on Remedying Environmental Damage, the main aspects of the draft Directive are described.

3.4.1. The "Channelling" of Liability

Article 3 of the proposal from 1991 poses the principle of the liability of the waste producer for damage and impairment of the environment caused by waste, irrespective of fault on the part

of the producer. Simultaneously, the proposal is intended to implement the polluter-pays principle. However, this principle – the legal ambit of which remains ill-defined – does not necessarily imply a strict liability regime. A liability regime based on the polluter's fault would be compatible with this principle if the regime ensures that the polluter actually suffers the consequences of the pollution. The Commission's choice of a strict liability regime channelled onto the producer is explained by the concern to use civil liability as an instrument to eliminate or reduce waste. Such an objective, however, has no direct relation to the function of civil liability, which is to ensure compensation of damage arising from wrong use or handling of products whether they are waste or not.

A positive feature of the proposal is Article 2.2.C., providing a transfer of liability whenever the producer delivers waste to a licensed or approved treatment or disposal facility. Applying the same logic, it is difficult to see how a similar transfer of liability would not occur upon delivery to a licensed carrier.

3.4.2. Definition of the Producer

The Commission proposal refers to any person who, in the course of a commercial or industrial activity, produces waste and/or anyone who carries out preprocessing, mixing, or other operations resulting in a change in the nature or composition of this waste. Article 2(2), however, states that the following are to be deemed the producer of the waste:

"The person who imports the waste into the Community;

The person who had actual control of waste when the incident giving rise to the damage to or impairment of the environment occurred if the producer is not identified;

The person responsible for the installation, establishment or undertaking where the waste was lawfully transferred to such installation, establishment or undertaking licensed pursuant to Directive 75/442/EEC on waste (amended thereafter), 75/439/EEC on waste oils or 78/319/EEC on hazardous wastes (amended thereafter)."

The method chosen in the draft leads to a complex definition based on a system of references to previous Directives, all of them providing for treatment, storage, and disposal operations subject to licensing. This leads to a contradiction in the underlying philosophy when it "channels" liability onto the producer while acknowledging the responsibility of the operator or the person having "actual control" of the waste, but only in cases where the producer has not been identified.

3.4.3. The Concept of Waste

The Commission proposal refers to the definition of the original waste Directive 75/442/EEC, which was amended in 1991. Waste is defined under Article 1 (a) of the amended Directive (91/156/EEC) as any substance or object in the categories set out in Annex 1 that the holder discards or intends or is required to discard. The concept of waste is rather broad by definition but excludes, for instance, gaseous effluents emitted to the atmosphere, radioactive waste, waste arising from mining operations, and decommissioned explosives. Given the fact that the definition is also fundamentally based on a subjective approach – the intent of the holder is decisive – judging whether or not a certain material is waste is far from simple. The categories set out in the mentioned annex do not make this easier, giving only rough examples of what should be considered waste.

Problems related to the definition of waste would complicate implementation of the Directive proposal. Different interpretations of waste in various Member States might also distort competition. Problems related to the definition have been under discussion for years, but a satisfying solution has not yet been found. Finally, one more question is still to be raised: Why is a harmonization of civil liability laws required especially for damage caused by waste? Would that not create an uneven situation when other possible sources of damage are left untouched?

3.4.4. Insurance and Compensation Fund

Article 11 of the draft Directive states the obligation of the producer, who produces waste in the course of a commercial or industrial activity, and of the eliminator of waste to be covered by insurance or other financial security. The article

also provides for the Commission to study the feasibility of establishing a European fund for compensating damage caused by waste when the person liable cannot be identified or is incapable of providing full compensation.

3.5. Civil Liability for Damage Caused during the Carriage of Dangerous Goods by Land: The Convention of October 10, 1989

The International Institute for the Unification of Private Law and the United Nations Economic Commission for Europe have actively cooperated in framing an international instrument on liability and compensation for damage caused during the carriage of dangerous goods by road, rail, and inland waterways. Prepared within the Institute of Rome, the draft was subsequently forwarded to the UN Economic Commission for Europe. CEFIC, along with other international organizations representing transport and insurance interests, participated as an observer in the work of UNIDROIT and the United Nations. The draft convention was finalized at the extraordinary session of the Inland Transport Committee of the UN Economic Commission for Europe, held in Geneva from October 2 – 10, 1989.

The main thrust of the Convention rightly establishes the linkage between civil liability and operational responsibility. This last, dated October 10, 1989, has been open for signature by the states since February 1990. Five ratifications are required for it to come into force. Among the countries that expressed at that time their active support are West European countries (especially The Netherlands, Denmark, the Federal Republic of Germany, and France with some reservations, Finland, and Austria) and also Central and Eastern European countries, and the United States.

The salient features of the Convention are as follows:

1) A "strict" liability regime is in effect.
2) For the purposes of the Convention, carriage comprises the period from the beginning of loading of goods to the completion of unloading operations.
3) Liability is channelled onto the carrier (save in the case of loading or unloading when such operations are carried out under the control of another person).
4) Reference is made to the ADR list for the definition of substances to which the Convention will apply (including hazardous wastes).
5) The principle of compulsory insurance (or any system of equivalent financial security) exists.
6) Total financial liability of the carrier (road, rail) is limited to a ceiling of 30×10^6 € per vehicle (18×10^6 € for personal injury; 12×10^6 € for damage to property and the environment). In the event of the "personal injury" ceiling being used up, the amounts of unmet claims for personal injury could compete with claims for damage to property within the "damage to property" ceiling. The liability ceiling specified for inland waterway transport is 15×10^6 € (8×10^6 € for personal injury; 7×10^6 € for other damage).
7) The carrier (road, waterway) is defined as being the person having use of the vehicle. The carrier is presumed to be the person on behalf of whom the vehicle was registered. This presumption may be reversed.
8) The rail carrier is defined as being the person(s) operating the railway on which the incident giving rise to damage occurred.
9) Grounds for exemption from liability are based on:
   Lack of information by the shipper or any other person as to the nature of the goods
   The fact that a third party acted or failed to act with intent to cause damage
   Deliberate fault of the injured party
   Occurrence of certain exceptional events: act of war, civil war, or natural phenomena of an exceptional and irresistible nature
10) The definition of "damage" is extended to cover ecological damage in addition to the more traditional categories of "death or personal injury" and "damage to property." Ecological damage is defined as "any loss or damage by contamination of the environment caused by dangerous substances, provided that the compensation for impairment of the environment . . . is limited to costs of reasonable measures of reinstate-

ment actually undertaken and to be undertaken."

The states will, however, be able to introduce some reservations if they so wish (particularly concerning defenses and the limiting of liability). From the economic and practical standpoints, it does not look as though the Convention will result in upheaval in land or rail transport. The Conseil des Bureaux (international insurers' body designed to facilitate the settlement of damage caused by automobile traffic – "green card system") has stated that the "green card" system will adapt fairly easily to the introduction of the Convention into the laws of Member States. As far as rail is concerned, the vast majority of railway companies have their own systems of insurance coverage. The Convention is, by contrast, a novelty for waterway transport, for which no compulsory insurance regime has existed up to now.

The authors of the draft have forwarded a resolution to the International Maritime Organization for a similar convention to be adopted for maritime transport, thereby complementing the work carried out in regard to land transport.

3.6. Liability in Connection with the Carriage of Dangerous Substances by Sea (HNS)

The adoption of an international draft convention on civil liability has for some years been included in the agenda of the IMO Legal Committee. An initial draft based on a "two-tier" system of liability – both complicated and costly – failed to achieve adoption in 1984. Despite this setback, the International Maritime Organization still sees the issue as a priority. The IMO Legal Committee is discussing several alternatives:

Alternative 1:
Sole liability of the shipowner coupled with a general raising of amounts of the total limitation stipulated in the 1976 Convention on the Limitation of Liability for Maritime Claims (CLLMC).

Alternative 2:
Sole liability of the shipowner coupled with an additional specific amount provided for in the CLLMC Convention for damage caused by HNS substances.

Alternative 3:
Shipowner liability limited in accordance with the provisions of the CLLMC and complemented by compulsory insurance, the cost of which would be borne by the shipper.

Alternative 4:
Shipowner liability limited in accordance with the provisions of the CLLMC and complemented by a fund financed by the shipper through either a pre- or a post-event financing mechanism.

Other options are possible, including the adoption, envisaged at the beginning of 1994, of a maritime carrier liability regime complemented by setting up an international compensation scheme, to come into operation beyond the limits provided by the shipowners' liability coverage or when the person responsible is not solvent. The system would be based on financial contributions calculated as a function of the type of cargoes and their hazard. Various options have been discussed, including the possibility of requesting importers, not shippers, to contribute. In any event, users of transport services would be asked to contribute.

The issue of adoption by the IMO of an international convention on liability and compensation is expected to be addressed in a 1996 diplomatic conference and will remain an important priority in years to come.

3.7. The Council of Europe Convention on Compensation for Damage Caused by Dangerous Activities

3.7.1. Background

In the 1986 Oslo Conference of European Ministers of Justice, the decision was taken to consider options to extend the reach of civil law to promoting environmental protection. Accordingly, the European Council of Ministers Committee set up a committee of experts in 1987 to propose measures for compensation for damage caused to the environment.

After its sixth meeting, the committee of experts instructed the Secretariat General and the Legal Affairs Directorate of the Council of Europe to prepare an interim activity report. This report was to be submitted to the European Committee on Legal Cooperation (CDCJ), a senior Council of Europe body in the legal field, and to Member States of the Council. The report enclosed preliminary draft rules on compensation for damage resulting from dangerous activities. The content of the Convention was adopted by the European Council of Ministers on March 24, 1993. The Convention was opened for signature on June 21, 1993 in Lugano and was signed by seven Council of Europe Member States (Cyprus, Greece, Finland, Italy, Liechtenstein, Luxembourg, and The Netherlands). Other countries were expected to follow suit, and debate within the European Union concerning the Commission's Green Paper has directly influenced this process.

The main aim of the Convention is to ensure prompt and effective compensation of damage to people, property, and the environment during the exercise of dangerous activities carried out in a professional capacity in installations or on sites. As stated in Article 1 of the Convention, it aims at providing adequate compensation for damage resulting from activities that are dangerous to the environment and also provides means of prevention and reinstatement.

3.7.2. Key Features of the Council of Europe Convention

3.7.2.1. Liability Regime

The Convention provides for a regime involving strict (no-fault) liability of "the operator of a dangerous activity." The operator's responsibility is not based on the concept of fault, but on the causal link existing between the damage caused and the incident occurring at the time or during the period when the operator was in charge of a dangerous activity. This general approach is in line with the one persistently advocated by the author and CEFIC, which have always wanted to see a strict link maintained between civil liability for damage and operational responsibility. The explanatory report to the Convention rightly points out major reasons for making the person in charge of the activity from which the damage resulted bear the cost of damage; the activity of this person is the source of the damage, and this person is best placed to prevent the damage and limit its extent.

3.7.2.2. Concept of Operator

The operator, as already discussed above, is defined as being "the person who exercises the control of a dangerous activity." Essential in determining who is in charge of a certain activity is to consider who has the power to decide on the way in which the activity is carried out.

3.7.2.3. Incident

Incident is defined as any sudden occurrence or any series of occurrences having the same origin that cause damage or create a grave and imminent threat of damage.

3.7.2.4. Concept of Dangerous Activity

Dangerous activity is defined as being "one or more of the following activities provided that it is performed professionally, including activities conducted by public authorities:

1) The production, handling, storage, use, or discharge of one or more dangerous substances or any operation of a similar nature dealing with such substances;
2) The production, culturing, handling, storage, use, destruction, disposal, release, or any other operation dealing with one or more:
   - Genetically modified organisms which as a result of the properties of the organism, the genetic modification and the conditions under which the operation is exercised, pose a significant risk for man, the environment or property;
   - Microorganisms which as a result of their properties and the conditions under which the operation is exercised pose a significant risk for man, the environment or property, such as those microorganisms which are pathogenic or which produce toxins;

3) The operation of an installation or site for the incineration, treatment, handling, or recycling of waste, such as those installations or sites specified in Annex II, provided that the quantities involved pose a significant risk for man, the environment or property;
4) The operation of a site for the permanent deposit of waste.

Dangerous substances , in turn, are defined as follows:

1) Substances or preparations which have properties which constitute a significant risk for man, the environment, or property. A substance or preparation which is explosive, oxidizing, extremely flammable, highly flammable, very toxic, toxic, harmful, corrosive, irritant, sensitizing, carcinogenic, mutagenic, toxic for reproduction, or dangerous for the environment within the meaning of Annex I, Part A to the Convention shall in any event be deemed to constitute such a risk;
2) Substances specified in Annex I, Part B to the Convention. Without prejudice to the application of sub-paragraph a above, Annex I, Part B may restrict the specification of dangerous substances to certain quantities or concentrations, certain risks or certain situations."

The operators of waste installations and sites for permanent waste deposit are explicitly subject to the new system. However, specific transitional provisions and liability rules are to be applied in the case of permanent waste deposit.

3.7.2.5. Concept of Damage

The concept of damage is defined as follows:

1) Loss of life or personal injury
2) Loss of or damage to property other than to the installation itself or property held under the control of the operator, at the site of the dangerous activity
3) Loss or damage by impairment of the environment in so far as this is not considered damage within the meaning of the preceding subparagraphs, and provided that compensation for impairment of the environment, other than for loss of profit from such impairment, is limited to the costs of measures of reinstatement actually undertaken or to be undertaken
4) The costs of preventive measures and any loss or damage caused by preventive measures, to the extent that the loss or damage referred to in subparagraphs (1) to (3) arises out of or results from the hazardous properties of the dangerous substances, genetically modified organisms, or waste.

The Convention covers legal categories traditionally included under the concept of "damage" in civil law (i.e., loss of life or personal injury). Additionally, the text introduces the concept of loss or damage by impairment of the environment, provided compensation is limited to the costs of measures of reinstatement actually undertaken or to be undertaken. Since "the environment" is defined in a remarkably broad way, the Convention potentially goes beyond the precedents established in the UNIDROIT Convention or in the EC draft Directive on liability for waste.

3.7.2.6. Environment

As already mentioned, the word "environment," in the confines of the Convention, includes the following factors:

1) Natural resources both abiotic and biotic, such as air, water, soil, fauna, and flora and the interaction among these factors
2) Property that forms part of the cultural heritage
3) Characteristic aspects of the landscape

The definition contained in the Convention is not exhaustive. On the contrary, the explanatory report to the Convention explicitly states that damage to any other aspect of the environment may also give rise to liability under the Convention. Even without this note, the definition is considered broad. Point (1) covers the factors traditionally understood to constitute "the environment." Points (2) and (3) refer to more immaterial values.

A legal definition of the environment (or damage to the environment) will influence the process of determining the type and scope of the necessary remedial action. The Commission Green Paper on Remedying Environmental

Damage refers to this definition of the environment and also notes the problems related to the matter.

3.7.2.7. Right of Action of Private Groups

Article 18 of the Convention to some extent authorizes actions by private associations that according to their statutes, aim at the protection of the environment, while it restricts the scope of such actions before the courts:

1) Requests for prohibition of any unlawful dangerous activity posing a grave threat of damage to the environment
2) Requests for an order to the operator to prevent an incident or damage
3) Requests for an order after an incident to prevent damage or reinstate the environment

3.7.2.8. Causal Link and Administration of Proof

According to Article 10, while maintaining the requirement of a causal relationship between the incident giving rise to damage and the activity of the operator, the court "shall take due account of the increased danger of causing such damage inherent in the dangerous activitiy."

3.7.2.9. Financial Security Scheme

According to Article 12 of the Convention, each Member State shall ensure that where appropriate, taking due account of the risks of the activity, operators conducting a dangerous activity on its territory be required to participate in a financial security scheme or to have and maintain a financial guarantee up to a certain limit, of such type and terms as specified by internal law to cover the liability under this Convention.

The article leaves a lot of freedom for national legislators, because it provides for a financial security scheme for operators covered by the Convention where appropriate, of the type and to such a limit as wanted, respectively. This solution is to be welcomed as leaving Member States free in a matter that does not require strictly prescribed international rules.

3.7.2.10. Access to Information

A system of access to information held by authorities or operators is also contained in the Convention. The same system explicitly recognizes the right to protect the confidentiality of data. The system is based broadly on the provisions of Community law governing the subject.

3.8. The 1993 European Commission Green Paper on Remedying Environmental Damage

In addition to international organizations, new civil liability regimes have been enacted by various EC Member States. In its Green Paper on Remedying Environmental Damage of 1993, the European Commission assumed that different approaches adopted might lead to distortion of competition and hamper the smooth operation of the single market. For this reason, the Commission suggested that a Community system of civil liability in relation to activities dangerous to the environment was necessary. Civil liability is also considered to belong to the domain of the Community legislation, since it presents many interfaces with EC environmental policy.

The purpose of the Green Paper, adopted in March 1993, is to inspire discussion on whether and how requirements to remedy environmental damage might be introduced appropriately and effectively within the Community to recover the costs of such restoration [47]. As its name envisages, the communication is a discussion document that does not formally propose a certain regime on the matter. Instead, it presents alternatives for the legislator and summarizes different arguments for and against different solutions. Nonetheless, the document outlines the main principles as follows:

1) The Commission aims at harmonization of civil liability systems for environmental damage in cases when a liable party can be identified, and it expresses a clear preference for strict (objective) liability, e.g., as defined in the Council of Europe Convention
2) Civil liability is not seen as a means for compensating damage when no liable party can be found; thus, the Green Paper looks for another kind of compensation mechanism, such as a collective compensation fund

Therefore, the Commission aims at a strict liability regime combined with a nonliability-related system (i.e., the cost of repair could be shared among several economic sectors).

The Green Paper suggests that such a joint compensation mechanism is needed in the event of the following:

1) Damage is unbounded or latent
2) Cumulative acts or incidents have occurred
3) Liable parties cannot be identified
4) No basis exists for liability
5) No causal link is determinable
6) No party has a legal interest to bring action

Questions to be answered are on whom the burden to contribute to such funds should rest and whether such funds are necessary in addition to existing mechanisms. The Green Paper does not provide the answer but asks whether the polluter-pays principle should be respected to the greatest possible degree so that contributions are requested from "the economic sectors most closely linked to the type of damage needing restoration." However, a number of difficulties exist in interpretation of the principle and in identification of those sectors. For example, should the "sector" that is today most closely linked to the damage pay for damage caused by operators in the past? In addition, the identification of sectors that are most closely linked to the damage raises serious principle and technical objections. It can be argued that postpollution, unrelated to faulty or illegal pollution, is the result of a given stage of development of society. Therefore, collective and public law answers and compensation are more suitable for such "historic" pollution.

Apart from the U.S. Superfund [Comprehensive Environmental Response Compensation Liability Act 1980 (CERCLA)] and the funds established by the oil industry [Brussels Convention on the Establishment of an International FUND for Compensation for Oil Pollution Damage (1971) and parallel financial structures, such as TOVALOP (Tankers Owners Voluntary Agreement Concerning Liability for Oil Pollution), CHRISTAL (Contract Regarding Interim Supplement to Tanker Liability for Oil Pollution), and OPOL (The Offshore Pollution Liability Agreement)], such compensation schemes are still unusual and of minor significance. In the Netherlands, a fund on damage from air pollution was created in 1972. In France, a fund for noise, which compensates persons living around Paris airports, was created in 1973. The U.S. Superfund, as is widely agreed, has proved inefficient and unfair and therefore should not serve as a model. Solutions for the oil industry, in turn, serve only for purposes characteristic of that industry (i.e., those resulting from major transport accidents).

The Green Paper considers a number of issues related to civil liability and aims at stimulating discussions among all interested parties. Therefore, it has a major role in opening discussions on the fundamental principles of Community environmental policy and also on the Community's role and need for harmonization in this area. The Council of Europe Convention recently adopted will, without doubt, have a great influence on the discussions since although it is binding on only a few states so far, it is the first existing international legal instrument covering civil liability in the context of dangerous activities for environmental damage as well as damage to persons and property.

The communication does not suggest any definition of environmental damage but merely refers to definitions contained in the Council of Europe Convention and in the amended proposal for a Council Directive for damage caused by waste. However, the fundamental importance of and difficulties related to the definition are emphasized.

3.9. Economic Aspects and Questions Bearing on the Insurance of the Industrial Risk

In the last few years, industry has encountered growing difficulties in renewing its "civil liability operation" insurance policies, in terms of both the cost of premiums and the extent of risks covered. Insurance companies, as well as the reinsurance market, have been very hesitant, chiefly for the following reasons:

1) The impact of the U.S. liability crisis, characterized by the number and magnitude of claims for damages
2) Fear of a similar situation developing in Europe, particularly in view of the introduction

of new liability laws and increasingly stringent technical Regulations
3) The potential liability of businesses involved in actions understood to be based, among other things, on damage to the environment whose cause is uncertain
4) Anticipated development at the national and international levels of new laws that would deal specifically with liability for pollution

This situation has prompted industry to study new additional methods of risk financing. In the United States, chemical and insurance companies alike have created insurance pools to increase available capacity.

In Europe, industry has found it increasingly difficult to find appropriate coverage, especially for "gradual pollution." Studies are therefore being undertaken to assess the "feasibility" of and arrangements for setting up a European Industrial Insurance Pool designed to provide added capacity and better conditions. Coverage of major industrial accident risks and of the risk of environmental pollution is reportedly being envisaged in particular. However, the actual adoption and operation of a pool depend largely on the development of the traditional insurance market. In many cases, conditions surrounding the renewal of policies can be said to have improved in recent years. One reason for this favorable trend could be that the envisaged creation of an insurance pool under direct industry control has served to make the insurance market more buoyant. The concept of a pool has rightly been perceived as mirroring the grave concern of industry and as offering an alternative to insurance mechanisms that no longer appear to be meeting industry's demand adequately.

The insurance crisis has not disappeared, however. Its acuteness has merely been mitigated a little. Major incidents or legislative initiatives unreasonably extending the scope of industrial civil liability could adversely affect the world insurance and reinsurance market, especially in the area of pollution.

3.10. Conclusions

Seeking harmonization of civil liability laws for all European Community member countries was the basis of the "product liability" Directive. Harmonization, or at least approximation of laws regarding liability for dangerous activities, was offered as a working hypothesis in the Green Paper published by the European Commission in 1993.

The issue could, however, be addressed in an even wider context, given that other economic or geographic areas might be affected by the transfrontier effects of pollution, as illustrated by major industrial accidents outside EC territory. With regard to the European Community, a harmonization of national laws is to be supported, if it eliminates trade distortions and simplifies existing provisions. A harmonization of this kind could, moreover, be achieved in a broader framework than that of the Community. However, real harmonization – a simplification of laws and a reduction of potential conflicts – is a most difficult and challenging task for lawmakers. No genuine harmonization can be achieved in this area without parallel progress in harmonization of the procedural rules governing civil liability. Therefore, this is the beginning, not the end, of a complex process.

The U.S. liability and insurance crisis has demonstrated that the dilution of basic legal requirements related, for example, to causation and evidence can lead to complete economic and legal failure. The question of need, justification, and possible creation of nonliability-related compensation mechanisms will have to be addressed carefully in the coming years, especially in relation to compensation for "historic" gradual nonattributable pollution damage and old dumping sites. Public authorities, the chemical industry, the insurance world, and the public at large have a joint interest in finding consensus-based solutions in a most important societal issue as the 20th century draws to a close.

4. Waste Shipments in the European Union: The Interface between Environmental Regulation and the Internal Market

4.1. Introduction

The last few years have seen an increase in the interaction between international trade policies and environmental protection. The first international convention on this subject was the

1933 Convention Relative to the Preservation of Fauna and Flora in Their Natural State. However, until the late 1980s, environmental regulators were developing their policies in large part separately from economic or trade considerations. This situation is changing rapidly, and today almost every international, intergovernmental organization has a program on trade and the environment. Moreover, environmental considerations are addressed as integral components of trade policy decisions, and trade or economic implications of environmental regulations are, conversely, being seen as key components of environmental regulatory decisions as well.

What is responsible for this dramatic change? First has been an increased recognition of the need to focus on transnational pollution issues such as the question of carbon dioxide emissions, chlorofluorocarbons (CFCs), and industrial accidents, for example, the Sandoz Rhine river pollution case. These transnational issues are increasingly addressed by multilateral environmental agreements, which also contain trade provisions. One example is the Montreal Protocol on CFCs of the United Nations Environment Programme (UNEP, 1987). Another example is the Basel Convention on Control of Transboundary Movements of Hazardous Wastes (UNEP, 1989).

In addition, focus has increased on the impact on competitiveness caused by some countries' having strict environmental standards or by attempts by such countries to erect barriers against imports produced in countries having less stringent environmental standards. This has led international, intergovernmental organizations, such as the General Agreement on Tariffs and Trade (GATT), to address the danger of countries taking unilateral actions under the guise of protection of environment, health, or safety, with the effect (and perhaps even the intention) of discriminating against imports. Included here would be such unilateral actions as discriminatory product standards, testing/certification requirements, and environmental subsidies.

A series of GATT disputes have been related directly to environmental regulation brought under the GATT nondiscrimination and national treatment provisions. In addition, the GATT, now the World Trade Organization (WTO), has instituted a Trade and Environment Program to facilitate the enforcement of "free" trade principles while simultaneously encouraging sustainable development.

Related subjects involve the effect of environmental policies of the developed or "Northern" countries on developing or "Southern" countries. Complicated issues of market access, technology transfer, commodity pricing of natural resources, debt levels, paternalism, and protectionism must be addressed here.

Regrettably, writings on the subject of free trade and environmental regulation tend to represent one polarized view or the other, either environmental protection or free trade. On the *free trade side*, the position is that environmental objectives do not justify violating the multilateral trading system rules of national and nondiscriminatory treatment. Moreover, the free traders believe that the sovereignty of countries in setting their own environmental priorities and requirements should be respected; that environmental policy should not impede the free flow of goods, services, persons, and capital; and that international environmental issues, while perhaps a component of trade policy, should be subservient to trade policy in the event of a dispute.

In contrast, *environmentalists* generally believe that economic expansion leads to environmental degradation; that harmonized standards reduce environmental protection; that unilateral trade-restrictive actions are valid or even desirable to promote domestic or global environmental objectives; and that environmental subsidies and other incentives or disincentives should be encouraged. The environmentalist perspective is not concerned with what it perceives as "outdated" issues of nondiscriminatory trade. Protection of the environment justifies almost any measures necessary.

4.2. European Community/Union Measures

In the European Community/Union, the interrelationship between trade and environmental regulation is best seen in the development of the Internal Market.

4.2.1. The Internal Market, "1992"

The Treaty of Rome was enacted in 1957 to establish the European Economic Community

and to guarantee, among members of the Community, four basic freedoms: the free movement of goods, persons, services, and capital between Member States.

The concept of 1992, "the Internal Market," was one of the best public relations coups in recent political history. Under the Treaty of Rome and other early documents of the European Economic Community, a single market and the elimination of physical, technical, and fiscal barriers (explanation see below) between Member States of the Community had already been anticipated. However, discouraged by the slow progress toward such a single market, the Community developed the 1992 program to accelerate its progress.

The first major document in the 1992 process was the White Paper on Completing the Internal Market [49]. It was published in 1985 and included a variety of proposals for legislation and timetables in which the 300-plus measures necessary to eliminate barriers to the free movement of persons, goods, services, and capital in the Community had to be enacted by the end of 1992. The barriers the Community was trying to eliminate among its Member States were physical, technical, and fiscal ones.

Physical barriers are such things as customs services, passports, and transport formalities. *Technical barriers* include health and safety requirements, standards, and product packaging. *Fiscal barriers* are among the most difficult to eliminate. Included here are harmonization of general tax rates and value-added tax (VAT) rates. Of the 300-plus measures necessary to implement the Internal Market, between one-third and one-half were environmental, health, and safety initiatives.

4.2.2. The Single European Act (see Section 2.1)

The Single European Act took effect on July 1, 1987 (Single European Act, signed at Luxembourg on February 17, 1986, and at The Hague on February 28, 1986). It contains numerous provisions amending the Treaty of Rome, many of which were necessary for the 1992 process to be successful. The most significant provisions affecting trade and waste shipments are the following:

1) Inclusion of a new Article 100 A in the Treaty of Rome providing that harmonization measures can generally be adopted by the Council by a qualified majority vote, rather than by unanimity as before
2) Inclusion for the first time in the Treaty of Rome of provisions specifically relating to environmental protection
3) Revision of the consultation procedure with the Parliament, giving Parliament a stronger role in the policy-making process

New Article 100 A of the Treaty of Rome (Article added by Article 18 of the Single European Act) provides that measures can be adopted by the Council by qualified majority, if their objective is the approximation of the provisions of national laws in order to further the establishment and functioning of the Internal Market, i.e., harmonization measures (see Section 2.1).

In the past, Council decisions had to be reached on a unanimous basis. As result, many Council actions, especially controversial ones, were deadlocked because one or another Member State could not agree with the rest. To facilitate action on measures necessary to implement the Internal Market, a new Article 100 A was included to permit the Council to act on Internal Market measures by qualified majority vote. (The votes of the Council are weighted. The total number of votes among the 12 Member States is 76; a qualified majority consists of 54 votes.) Exemptions from qualified majority voting exist here for measures related to fiscal provisions; worker rights issues; as well as health, safety, environmental, or consumer protection issues. Here, unanimity still had to prevail under the Single European Act.

Enactment of Community legislation by unanimous Council votes is usually more complicated and time consuming than reaching qualified majority decisions. One of the early steps in the EC legislative process under the Single European Act, therefore, always involves "jockeying for position" between the European Commission and Member States to determine the legislative basis of the measure in question. A dispute on the legal basis of a piece of Community legislation concerning titanium dioxide went as far as the European Court of Justice [50]. In this case, the Court of Justice ruled on the legal basis of Community legislation that was aimed both

at the achievement of the Internal Market and at environmental protection. The Court upheld the legal basis of the legislation as an Internal Market, rather than environmental, measure and annulled the Directive. The Court ruled that the choice of legal basis should be governed by the aim and content of the legislation in question.

As stated above, the Single European Act also specifically provides that protection of the environment is a valid area of Community legislation. In practice, the Community began legislating in the environmental area in the late 1960s. However, the original Treaty of Rome is primarily a trade agreement and does not specifically provide authority for such legislation. Under the Single European Act, the Community must now consider environmental implications in adopting its other legislation, as well [51]:

"Action by the Community relating to the environment shall be based on the principles that preventive action should be taken, that environmental damage should as a priority be rectified at source, and that the polluter should pay. Environmental protection requirements shall be a component of the Community's other policies."

The Member States were rather suspicious of this amended Treaty language, since environmental, health, and safety regulation had traditionally been within their own purviews. Therefore, the Treaty language now also includes two other provisions: (1) the issue of subsidiarity (see Section 2.1), and (2) unanimous voting on environmental matters. "Subsidiarity," a term that has received much attention in the context of the Maastricht Treaty, in this environmental context, means merely that environmental legislation or enforcement should be undertaken at the lowest feasible regulatory level.

New Article 130 T of the Treaty of Rome [51] specifies that Member States will not be prevented from adopting more stringent protective environmental measures than those enacted at the Community level, provided these measures are compatible with the Treaty of Rome (see Section 2.2). This is very useful for Member States, such as Denmark, the Netherlands, and Germany, that periodically adopt more stringent legislation. At the Community level, there has also been a trend to "harmonize up" (i.e., to harmonize toward more stringent environmental regulation). Invariably, the Community has usually taken existing legislation from one of the more stringently regulated Member States as a model for its own Community-wide legislation.

A number of procedural changes also occurred as a result of the Single European Act, the majority of which increased the power of the European Parliament. The general procedure of parliamentary advisory review for Community actions is one of the Commission proposing legislation and the Council acting on it. Prior to such Council action, Parliament and ECOSOC review the proposal and issue advisory opinions, which the Commission and/or Council can accept or reject.

The Single European Act introduced another procedural step in certain situations, the so-called Cooperation Procedure. Under this procedure, two readings in the Parliament and two Council reviews (under new Article 149, as replaced by Article 7 of the Single European Act) take place.

4.2.3. The Maastricht Treaty – Environmental Provisions [52]

Mention should also be made of the environmental provisions of the Maastricht Treaty. The Maastricht Treaty was agreed to by the Heads of State and Government of the European Community Member States in December 1991, to revise the Treaty of Rome to provide for such changes as gradual political integration, a common currency, and a Single European Bank.

The Maastricht Treaty is notable for its further integration of environmental considerations into all other policies of the European Community; the text goes even further than that of the Single European Act. (Since the entry into force of the Maastricht Treaty changed the name "European Community" to "European Union," henceforth, reference is to either the European Union or the EU, even though the measures described may have been initiated in EC times.) It also contains language on the interrelationship between transportation, energy, and agricultural policies and environmental protection. Moreover, the Treaty deals with the need to consider trade or competition and economic development issues within the framework of environmental considerations. In fact, protection of the environment is explicitly contained in the introductory section of the Maastricht Treaty (i.e.,

impact on the environment should be considered in the development of all other EU policies and the EU has competence to regulate in this area). The concept of "sustainable development" is also found in this Treaty.

The Treaty also eliminates the need for unanimous votes for environmental measures and adds a new "Cooperation Procedure" which expands the role of the European Parliament. In addition, the question of the meaning of "subsidiarity" is supposedly clarified. However, confusion about the exact definition of this term, and when it is to be applied, is still present under this new Treaty.

Finally, the Maastricht Treaty provides for the creation of a "Cohesion Fund" to assist the least financially sound of the European Member States, Ireland, Spain, Portugal, and Greece (including to help them improve environmental protection and enforcement measures).

4.2.4. Other Applicable Provisions of the Treaty of Rome

Notification and Standstill Procedure on Technical Standards and Regulations. Significant European Court of Justice case law exists on "mutual recognition"; i.e., goods lawfully produced and marketed in one EU Member State must be accepted in all other Member States (except where refusal is justified by Articles 30 and 36). Directive 83/189/EEC [53] specifies notification procedures for technical standards and regulations in the EU. The procedure was developed to discourage national, unilateral actions in this area. Member States must inform the Commission on each draft technical standard or regulation. The Commission then informs the other Member States. The Commission and the other Member States have the option of consenting to the draft technical standard or regulation text. The acting Member States must take their positions into account. Waiting periods for adoption of the measure(s) are also specified.

Article 30. Article 30 of the Treaty of Rome provides that "quantitative restrictions on imports and all measures having equivalent effect shall be prohibited." Quantitative restrictions have never constituted a serious obstacle to intra-EU trade. Therefore, the emphasis in practice has been on measures having an "equivalent effect." All legislative rules and administrative provisions, as well as administrative practices that form a barrier to importation or exportation, are governed. Included here are provisions and practices that render importation or exportation more expensive or difficult compared to sales of home products on the domestic market. The *Cassis de Dijon* decision [54] established the basic principles to be applied in judging the legitimacy of measures adopted by EU Member States that hinder the free movement of goods among them. In the absence of harmonized EU law, Member States are free to establish rules affecting the free movement of goods.

However, goods lawfully produced or marketed in one Member State must be accepted in other Member States, except where refusal is based on the "rule of reason" or on exceptions provided in Article 36. The rule-of-reason exceptions are applicable only to noneconomic matters, i.e., (1) environmental protection, (2) consumer protection, (3) prevention of unfair commercial practices or (4) effectiveness of fiscal supervision – provided, however, that the national measure in question is not unreasonable, disproportionate, or protectionist. Exceptions provided in Article 36 include national restraints on trade, if necessary to protect (1) public morality, public policy, or public security; (2) health and life of persons, animals, or plants; (3) national treasures of artistic, historic, or archaeological value; and (4) industrial or commercial property.

However, not all trade restrictions based on the "rule of reason" or on Article 36 exemptions are acceptable. A restriction may not, for example, constitute a means of arbitrary discrimination or disguised restriction on trade between Member States. These concepts are referred to as the principles of "nondiscrimination" and "proportionality;" the restriction must apply equally to nationally produced goods and goods imported from other Member States and must be necessary to achieve legitimate, proportional objectives.

For environmental cases, there should also be a balance between environmental and free trade purposes. A regulatory measure must be necessary to achieve a stated goal, and no less restrictive measures can exist to achieve this goal.

A case in point is the Danish Bottles case [55], which demonstrates the complexities of justifying the compatibility of environmental measures with rules on the free movement of goods. In question was a Danish law providing that mineral water, soft drinks, and beer could be sold only in refillable containers. A deposit and return system to ensure refilling of a large portion of containers was also included. The result of this law was that beverages lawfully sold in other Member States could not be sold in the same containers in Denmark, a clear violation of Article 30 of the Treaty of Rome.

The European Commission took Denmark to the European Court of Justice to contest this legislation. The Court found that the Danish system of mandatory deposit on containers for mineral water, soft drinks, and beer, although placing a greater burden on non-Danish producers, did not infringe Article 30. The Court held that environmental protection is an objective that may justify restraints on trade. The Danish deposit system appeared necessary to attain the desired objective, and no other less restrictive means existed.

A more recent example of one State's unilateral trade action, ostensibly to protect the environment, is the German Packaging Waste Regulation [56]. Under it, a complicated take-back and recycling system for packaging and packaging waste (set up and funded by industry because of the constraints of the Regulation) imposes, in practice, significantly disproportionate problems on importers into Germany than on the domestic industry.

A number of complaints have been filed with the European Commission alleging Germany's violation of Article 30 of the Treaty of Rome. One benefit of the German Regulation is that it has resulted in the EC's accelerating the development of its own Directive on Packaging and Packaging Waste [57] to harmonize all EU Member State rules on this subject. Germany, however, has steadfastly opposed the text of this EC draft Directive and refused to amend its own Regulation. As a result, the European Commission decided, on July 6, 1994, to initiate legal proceedings against Germany because its unilateral packaging Regulation creates an unjustified barrier to trade between EU Member States. In all likelihood, this is merely a political ploy to get Germany to drop its opposition to the EC's draft Packaging and Packaging Waste Directive and to bring the German regulatory requirements for waste packaging into line with the EC Directive's requirements (i.e., reduce the German recycling and reuse targets and build up domestic German recycling capacity more rapidly).

4.3. Waste Shipments: Conflict between European Union Free Movement of Goods Principles and Environmental Regulation

4.3.1. The New Regulation 259/93: Introduction

Recent regulatory initiatives on waste shipments provide perhaps the most dramatic example of the conflict between the European Union's principles of free movement of goods and environmental regulation. On May 6, 1994, the European Union Regulation "On the Supervision and Control of Shipments of Waste within, into and out of the European Community" [58] became effective (hereinafter Regulation 259/93). Regulation 259/93 imposes a complex system of shipment notification and consent on all shipments of waste, not just hazardous waste, that cross borders in the European Union, as well as all waste imports into and waste exports from the EU. Although the notification and consent procedures vary depending on the type of shipment, its destination, and its purpose; waste shipments for recovery or recycling operations are covered, as is waste for disposal.

Regulation 259/93 must be viewed in the context of other key EC waste legislation, most notably, Directive 75/442 EEC on Waste [59], as amended by Directive 91/156/EEC [60]; and Directive 91/689/EEC on Hazardous Waste [61], replacing Directive 78/319 on Dangerous Waste [62]. For these pieces of legislation, see → Waste, Chap. 2. International commitments of the EU on this subject (e.g., Basel Convention) are also interrelated.

On the specific topic of transfrontier movements of waste, the EEC had Regulations as early as 1984, with Council Directive 84/631/EEC, as amended [63], "On the Supervision and Control within the European Community of the Transfrontier Shipments of Hazardous Waste." Directive 84/631 required Mem-

ber States to take measures to ensure the supervision and control of transfrontier shipments of hazardous waste within, into, and out of the Community to protect human health and the environment.

Under Directive 84/631, all cross-border movements of hazardous waste were subject to a notification requirement to be effected by a uniform Consignment Note and typically made to the Competent Authority of the Member State of destination. Procedures for acknowledgment of and objections to the shipment, if any, were provided. However, given the narrow definition of "hazardous waste," Directive 84/631 applied to only a limited number of transfrontier shipments of waste. According to 1992 figures of the Organization for Economic Cooperation and Development, ca. 200×10^6 t of waste cross OECD borders each year (140×10^6 t cross EU borders). Of these 200×10^6 t, < 1 % was estimated by the OECD to involve so- called hazardous waste.

In addition, since this 1984 legislation was a Directive, EC Member States tended to implement it inconsistently. To fill this regulatory gap, address implementation inconsistencies, and adapt the rules regulating transfrontier movements of hazardous wastes to the requirements of the March 22, 1989 Basel Convention on Transboundary Movements of Hazardous Waste and Their Disposal and the Lomé Convention of December 15, 1989 (the Fourth ACP – EEC Convention), the European Council adopted the Regulation "On the Supervision and Control of Shipments of Waste Within, Into and Out of the Community" (Regulation 259/93). Since this legislation is in the form of a Regulation, as opposed to a Directive, it is directly applicable and binding on EU Member States.

Regulation 259/93 was also drafted to ensure consistency with the OECD, March 1992 Council Decision Concerning the Control of Transfrontier Movements of Waste Destined for Recovery Operations, specifically its "Green," "Amber," and "Red" Lists of Waste. These lists are categorized according to hazard ("Green" being least hazardous, with "Red" most hazardous) and appear at Annexes II through IV of Regulation 259/93. Regulation 259/93 was also deemed necessary to ensure continued and improved environmental protection in EU waste management, in view of completion of the Internal Market and its resultant removal of border controls.

Finally, the issues of waste management in general in the EU, and waste shipments in particular, are highly emotional and political ones. Regulation 259/93 is at least partially the result of successful political pressure by environmental groups, some Member State regulatory authorities, and "the public" for stricter and harmonized European Union legislation on this subject.

The overriding purpose of the Regulation is, of course, to ensure prior notification and consent for waste shipments to Competent Authorities, Member States, enabling them to be informed of the particular type, movement, and disposal or recovery of waste, so that they can take all necessary measures for the protection of health and the environment, including the possibility of raising reasoned objections to the shipments (e.g., de facto "PIC" or prior informed consent).

Regulation 259/93 provides for a Consignment Note notification system for the covered waste shipments to the Competent Authorities of destination, dispatch, and transit and to the consignee (see Sections 4.3.2.1 and 4.3.2.2). The content of the notification and the subsequent regulatory avenues available to the Competent Authorities to "control" these shipments depend on the nature and composition of the waste (i.e., its hazard); the shipment's purpose (disposal or recovery); and its destination (to or through other countries in the EU, to non-EU OECD Decision signatories, to other parties to the Basel Convention, to countries having equivalent bilateral or multilateral agreements with EU Member States – the possibilities are numerous).

The bases on which Member States may object to a waste shipment for disposal include the principles of proximity (waste should be disposed of near the point of generation – a policy encouraging local waste disposal); self-sufficiency (to ensure that each Member State can dispose of its waste in its own territory); and priority for recovery. Differing positions have been taken by commentators as to whether the first two of these principles can or should be extended to waste shipments for recovery under the Regulation. Political pressures by local authorities, NIMBY("not-in-my-backyard")-ism by the neighboring public if such an interpretation is

upheld, and resulting negative competitive impacts on industry in the EU can be anticipated if this interpretation is sustained.

4.3.2. Specific Provisions of Regulation 259/93

Exclusions from the scope of Regulation 259/93 are:

1) Offloading to shore of waste generated by normal operation of ships and offshore platforms, including wastewater and residues, provided that such waste is subject to a specific binding international instrument
2) Shipments of civil aviation waste
3) Shipments of radioactive waste
4) Shipments of waste already covered by other relevant legislation
5) Shipments of waste into the EU subject to the environmental protocol of the Antarctic Treaty
6) Shipments of waste contained on Annex II (the OECD Green List of Waste) destined only for recovery, subject to certain conditions

The main text of the Regulation is divided into sections, depending on whether the shipments are between EU Member States or involve imports or exports and, in each section, whether disposal or recovery is involved.

4.3.2.1. Shipments of Waste between EU Member States

Shipments of Waste for Disposal. If a notifier intends to ship waste for disposal from one EU Member State to another or pass it in transit through one or several other Member States, the Competent Authority of destination must be notified, and a copy of the notification must be sent to the Competent Authority of dispatch and of transit and to the consignee. Notification must also cover any intermediate stage of the shipment from the place of dispatch to its final destination. The notification is to be effected by means of a Consignment Note, which is to be issued by the Competent Authority of dispatch. In making the notification, the notifier must complete the Consignment Note and must supply any additional information and/or documentation requested by the Competent Authorities.

Moreover, the notifier must enter into a contractual agreement with the consignee for disposal of the waste. Specific provisions are included as acknowledgments of the Consignment Note and authorization of the shipments. The shipment may be effected only after the notifier has received authorization from the Competent Authority of destination.

To implement the principles of (1) proximity, (2) priority for recovery, and (3) self-sufficiency at the EU and national levels, Member States may take appropriate measures generally or partially to prohibit shipments of waste for disposal.

Shipments of Waste for Recovery. The notification requirements of Regulation 259/93 with respect to shipments of waste between Member States for recovery are generally consistent with the requirements described above for shipments between Member States for purposes of disposal, with certain key deviations. First, the content of the Consignment Note differs. Moreover, tacit consent for a shipment is deemed to exist if 30 days have passed following notification, and no objection has been lodged.

In addition, Competent Authorities with jurisdiction over specific recovery facilities may decide, notwithstanding the notification and consent requirements of the Regulation, that they will not raise objections concerning shipments of certain types of waste to specific recovery facilities. Such decisions may be limited for a specific time period and may be revoked at any time. The Commission must be notified of any such special arrangements; it will inform the Competent Authorities of the other EU Member States and the OECD. However, Member States of transit or dispatch may object.

Shipments of Waste within one Member State. The notification and consent provisions described above do not apply to shipments of waste within one Member State. Here, the individual Member State in question has the role of establishing an appropriate system for the supervision and control of shipments of waste, "coherent with" the system established by Regulation 259/93. The Member States must inform the Commission of these individual systems. However, shipments between Regions are covered if

the Region has jurisdiction over waste management (see also Section 4.3.3.1).

4.3.2.2. Exports of Waste from the EU

Exports for Disposal. Exports of waste from the EU for disposal are prohibited under Regulation 259/93, except to European Free Trade Area (EFTA) countries, which are also parties to the Basel Convention. Exports of waste for disposal to an EFTA country may also be banned if the EFTA country of destination prohibits imports of such waste, if it has not given its written consent to the specific import in question, or if the Competent Authority of dispatch in the EU has reason to believe that the waste will not be managed in accordance with environmentally sound methods in the EFTA country of destination.

The notification and consent requirements with respect to exports of waste from the EU for disposal generally track those described above for intra-Union shipments for disposal, with certain deviations. For example, the notification and consent time periods are significantly expanded here. The Regulation also contains language as to obligations of EU Customs offices of departure.

Exports of Waste for Recovery. Exports from the EU of waste destined for recovery are prohibited under Regulation 259/93, except for those exports to countries to which the OECD Decision applies and other countries that are parties to the Basel Convention (or with which the EU or the EU and its Member States have concluded bilateral, multilateral, or regional agreements/arrangements compatible with the Basel Convention and EU legislation). The Regulation also provides specific requirements that such agreements or arrangements must meet.

In addition to the procedures above, exports of waste from the EU for recovery to countries to which the OECD Decision, Basel Convention, and/or bilateral or multilateral agreements or arrangements apply may also be banned if the country in question prohibits all imports of such waste, if it has not given its consent to the specific import in question, or if the European Union Competent Authority of dispatch has reason to believe that the waste will not be managed in accordance with environmentally sound methods in the country of destination.

Generally, waste specified on Annex II of Regulation 259/93 (OECD Green List of Waste) for recovery is not subject to the notification and consent requirements of the Regulation, again with certain exceptions. First, the Commission is required to inform every country to which the OECD Decision does not apply of the waste categories contained in Annex II and request written confirmation that such waste is not subject to control in the country of destination and that the latter will accept such waste to be shipped without recourse to the control procedures. Annex II waste must be exported for recovery operations within a facility that is locally authorized and operating in the importing country. Moreover, such exports will be subject to surveillance.

As to exports of Annex III and IV waste for recovery (OECD Amber and Red Lists, respectively), the notification and consent procedures discussed earlier with respect to intra-Union shipments generally apply.

Finally, the Regulation provides that all exports of waste to ACP (African Caribbean, Pacific) States will be prohibited. This prohibition does not prevent an EU Member State to which an ACP State has decided to export waste for processing from returning that processed waste to the ACP State of origin.

4.3.2.3. Imports of Waste into the EU

Imports for Disposal. Imports of waste into the EU for disposal will be prohibited, except those from EFTA countries that are Parties to the Basel Convention, other countries Party to the Basel Convention, or countries that have concluded appropriate bilateral or multilateral agreements or arrangements with the EU as a whole or with individual Member States. Such agreements or arrangements must be notified to the European Commission, which will review them.

As in the case in the intra-EU and export shipment situations discussed above, notification of imports of waste for disposal will be subject to the Consignment Note procedure. Notification must be made to the Competent Authority of destination, and the Consignment Note will be issued by that Competent Authority. Again, spe-

cific deadlines for notification, objections, and decisions are provided.

Imports for Recovery. Imports of waste into the EU for recovery are prohibited under Regulation 259/93, with the exception of imports from countries to which the OECD Decision applies and, again, countries Party to the Basel Convention or with which the EU/Member States have concluded appropriate bilateral, multilateral, or regional agreements or arrangements.

The notification and control procedures of Regulation 259/93 also apply to waste imports into the EU for recovery from countries and through countries to which the OECD Decision applies for waste listed on Annexes III and IV of the Regulation or for waste that has not yet been assigned to an Annex.

4.3.2.4. Transit of Waste from Outside and Through the EU for Disposal or Recovery Outside the European Union

Here again, the Consignment Note and control procedures apply. The notification is to be effected by means of the Consignment Note sent to the last Competent Authority of transit within the EU, with copies to the consignee, the other Competent Authorities concerned, and the Customs offices of entry into and departure from the EU.

The shipment may be admitted into the European Union only if the notifier has received the written consent of the last Competent Authority of transit, which authority will also issue the Consignment Note. Specific time deadlines for notifications and decisions are also provided. Transits of waste listed on Annexes III and IV for recovery through one or more EU Member States from a country, and transit of waste for recovery to a country to which the OECD Decision applies require notification of all Competent Authorities of transit in the Member States concerned. Such shipments may be effected only in the absence of objections.

4.3.2.5. Common Provisions

Regulation 259/93 contains certain common provisions applicable to all shipments, whether they are for disposal or recovery, or involve waste imports, intra-EU shipments, or exports from the European Union. These cover general notification possibilities, illegal traffic, financial guarantees and insurance, inability to facilitate recovering disposal and return, regulatory authority designation, documents retention, etc.

4.3.3. The Trade – Free Movement and Environmental Protection Conflicts in Complying with EC Regulation 259/93

4.3.3.1. Definitions

One of the most difficult issues to anticipate in compliance with this new EC Regulation is a definitional one. Even though much progress has been made in the definitions of "waste" and "hazardous waste" in the OECD and in recent EC Directives on the subject, clear EC definitions have still not been developed, and differing EU Member State definitions continue to exist. Therefore, regulatory inconsistencies on this subject can be expected to remain.

One case in point is the German distinction between something having commercial value (Wirtschaftsgut) and waste, and the German treatment of secondary raw materials. However, the new German Federal Comprehensive Waste Reform Law (Kreislaufwirtschaftsgesetz) intends to change German waste definitions to comply with EU definitions. This law was finally passed by the Bundesrat before its summer 1994 recess and is expected to come into effect, at the latest, by 1996.

The EC Waste and Hazardous Waste Directives attempt to define waste in their texts. The definition of waste in the 1991 Waste Directive (91/156/EEC) is as follows:

"Waste" shall mean any substance or object in the categories set out in Annex I which the holder discards or intends or is required to discard" (Article 1).

The "hazardous" waste definition under the 1991 Hazardous Waste Directive (91/689/EEC) is much more complicated and includes various references to Annexes, origin, composition, properties, and a final umbrella category of "any other waste" considered by a Member State to be hazardous, in effect negating the usefulness of the harmonized European-level definition.

In addition, both the 1991 Waste and the Hazardous Waste Directives mandate the compilation of lists or catalogues of waste under their domain. The EU has published its Waste Catalogue [64] under the 1975 and 1991 Waste Directives [65], and the so-called Waste Catalogue II or List of Hazardous Wastes under the 1991 Hazardous Waste Directive was published on December 31, 1994 [66].

The process of developing both European Commission lists has been highly controversial. Officials at the Commission have taken varying positions as to whether these should be listings of products and substances or whether they should, instead, be criteria-based. Moreover, a number of key Member States, most notably Germany and France, are still lobbying to have the new European List of Hazardous Waste be similar to those in place in their countries (i.e., a listing of substances or products that have been found to be hazardous; therefore, waste containing any of these products or substances in whatever quantities would, likewise, be categorized as hazardous).

As was the case with Waste Catalogue I, the scope and content of the EU Hazardous Waste List (Waste Catalogue II) are of major importance to a number of industries and companies operating in Europe. The content of this new List will affect such commercial questions as whether and where a material can be recycled or remediated, whether it can be shipped across borders, and what other regulatory constraints and liabilities will apply vis-à-vis manufacturers, generators, and transporters. Sales price and contractual and marketing questions of customers are intricately involved here as well.

The new List of Hazardous Waste Pursuant to Article 1 (4) of Directive 91/689/EEC on Hazardous Waste (January, 1994), while still product related, deals only with broad product categories and is keyed to the thresholds and concentrations developed for hazardous properties under EU chemicals legislation [e.g., the 0.1 % concentration for category 1 and 2 carcinogens in the 1988 Preparations Directive (88/379/EEC)]. The inclusion of these thresholds and concentrations has been the subject of some controversy.

Wallonian Waste Decree. As illustrated in the German "Wirtschaftsgut" example above, another definitional issue of concern in complying with Regulation 259/93 is whether a material is a "product" or "good," hence coming under the Treaty of Rome's free movement of goods principles, or whether it is something else entirely. Under the new EC Regulation 259/93 and such recent legal interpretations as the July 1992 ECJ Judgment on Wallonian Waste Imports [67], waste should be granted special treatment for environmental protection purposes, tantamount to at least a partial exemption from the European Union's free movement of goods and Internal Market principles. This case was particularly interesting in that the Wallonian Decree at issue not only impeded the flow of waste across EU Member State borders, but also impeded intra-Belgian trade on a regional basis. While the ECJ held that the challenged Wallonian Decree did not conform to the 1984 Hazardous Waste Movements Directive (the precursor to Regulation 259/93), it found that the Decree's banning of the disposal of wastes in Wallonia that were generated outside Wallonia was not "discriminatory" within the meaning of the Treaty of Rome. This decision, was based on the "particularité" of wastes, in that Article 130 S of the Treaty of Rome requires that, as a priority, "environmental damage" should be rectified at the source. The Court also referred to the Basel Convention's principle of waste self-sufficiency.

The ECJ appears to have erroneously interpreted the Treaty of Rome provisions here. The Wallonian Decree clearly violates not only the 1984 Hazardous Waste Shipments Directive, but also the free movement of goods provisions of the Treaty of Rome. Relying on Article 130 provisions is also questionable since a Directive that deals with shipments of materials and border transfers within the EU should more appropriately be considered an Internal Market measure and, therefore, judged under Article 100 A of the Treaty of Rome, not Article 130 S.

In addition, because the Wallonian Judgment did not address all of the issues on this subject raised by Regulation 259/93, a definitive legal interpretation is needed on the free trade versus environmental protection argument for waste shipments in the EU.

Article 130 S vs. Article 100 A. The debate continues – the ECJ has just rejected the European Parliament's request to annul Regulation 259/93 because it was improperly based

on Article 130 S (environment) of the Treaty of Rome. The Parliament said that this Regulation was essentially an Internal Market (trade) measure, hence based on Article 100 A of the Treaty of Rome and subject not only to the Treaty's free movement of goods provisions, but also to Article 113 of the Treaty dealing with external trade (It is not just happenstance that an Article 100 A determination for the new Regulation would give the Parliament greater powers as to the form and content of the Regulation.) However, the ECJ rejected the Parliament's arguments and upheld the Article 130 S basis of the Regulation. Waste, it seems, is indeed special and, at least for now, will not be called a "good" in the EU.

The European Court of First Instance has also just rejected as inadmissible a request by two French waste management companies and one Luxembourg one that it annul Article 4 of Regulation 259/93, which permits individual Member States to ban imports of waste, even nonhazardous waste, from other EU countries. (At issue was a French Decree banning imports into France of household waste for disposal in landfill.) The Court of First Instance did not address the substance of the plaintiffs' complaint. Instead, the case was dismissed on the procedural ground of lack of "standing" of the plaintiffs, since they were not "directly concerned." In this ruling, the President of the Court said that Article 4 of the 1993 Council Regulation was not aimed at companies, "except in their objective quality as economic operators in the waste management and transport sector, the same as for any other operators in an identical situation." The Court's President also rejected the request for damages and interest. Case T-475/93, SA Buralux, SA Satrod, SA Ourry vs. Council of the European Union, judgment published in O.J.E.C. C188, July 9, 1994.

Disposal and Recovery. Another definitional concern with Regulation 259/93 is seen in the question of how to define "disposal" and "recovery." Member States of the European Union have, to date, taken inconsistent positions as to whether operations to be carried out are either of the two. This is obviously a critical point for purposes of defining the type of notification and the content of information to include in the Consignment Note under Regulation 259/93. Defining an operation as "recovery" or "recycling/further use," as opposed to "disposal," will also have a critical effect on how the proximity principle would apply. This issue is particularly difficult for operations involving energy generation and incineration.

Perhaps the most difficult practical problem resulting because of these vague definitions is in the area of waste for recovery. The impact on byproducts, coproducts, secondary raw materials, and product or container take-back programs must be clarified.

The practical, commercial difficulties posed by all of the above definitional issues for EU companies in attempts to adhere to Regulation 259/93 are discussed in Sections [**?**]. These problems are magnified even more in the international arena.

In addition to the dilemmas caused by inconsistencies between the EU-level definitions and those in some EU Member States, OECD and Basel Convention strictures, obviously, also have to be adhered to. It is already evident that definitional divergencies between these two organizations and the EU may cause problems in the future.

In addition, many affected companies are multinational enterprises, with manufacturing, waste-generating plants in and outside the EU. Company attempts to impose one comprehensive waste management scheme throughout all of such companies' international activities will be stymied. A case in point is seen in the differences in the U.S. and EU definitions of "waste," "hazardous waste," "disposal," and "recovery," and the shipment restrictions imposed. For example, unlike the ECJ, the U.S. Supreme Court has determined that waste is an article of commerce (i.e., a "good") meriting constitutional protection against discriminatory state and local Regulations that impede its free movement and that nothing special or distinctive exists in waste that should permit discriminatory restriction of its flow across state lines to apply in the United States.

A second example is seen in the fact that the United States attempts to define waste in a way that encourages beneficial recycling (exemption of certain kinds of materials destined for certain recycling). The EU definition follows a less desirable, inconsistent approach: It covers all secondary materials as "waste" as well, regardless

of whether disposed or recycled, but then differs in the regulatory treatment of conventional waste and recyclable waste.

Some parties, frustrated by these definitional differences and the length and complexity of the debate believe that "waste prevention" should be the focus in the future, instead of waste shipment restrictions, especially when the words "waste" and "hazardous waste" cannot even be defined properly.

4.3.3.2. Liabilities

An attempt must also be made to address liability issues under Regulation 259/93 at the EU level to ensure some degree of consistency in determining liable parties and in enforcement. From past experience, this issue cannot be left solely to the Member States. Adoption of EU legislation on Civil Liability for Damage Caused by Waste is a first step (see Section 3.4), but continued Member State inconsistencies on this subject will further confuse companies in compliance.

4.3.3.3. Administrative Issues

European industry, while favoring harmonized regulation of waste shipments throughout the EU, has raised some of the issues noted in the previous sections. However, it appears to be focusing currently on the failure of the EU and its Member States to provide the administrative structures and procedures to allow industry to comply with Regulation 259/93 by its effective date of May 6, 1994, or shortly thereafter.

Among the most active EU-level industry associations on this subject have been UNICE, Eurométaux (which has particular concerns about disruption of shipments of scrap metals as secondary raw materials), the European Chemical Industry Council (CEFIC), and the European Federation of Waste Management (FEAD). According to a UNICE discussion paper on the implementation of Regulation 259/93,

"... the adminstrative backup necessary for the proper implementation of the Regulation is widely lacking in most of the Member States. It is both paradoxical and disastrous for a Community Regulation, directly applicable according to Community law to be paralyzed in this way ...."

The concern about the lack of administrative systems in the Member States to implement the Regulation and the enormous burden to be placed on Competent Authorities in the Member States in homogeneous or integrated implementation is well justified. As noted in Sections [**?**], the notification and approval system under Regulation 259/93 is very complex and inconsistent, depending on the types of shipments, their purposes and destinations, and quite bureaucratic and paper-intensive. It is questionablewhether the Competent Authorities will be able to deal with the large number of notifications to be expected in the time anticipated by the Regulation. Given the large degree of discretion still left to the Member States in implementation, it is also questionable whether a truly harmonized system will evolve. Therefore, it cannot be expected that a significant degree of increased environmental protection will ensue as a result of Regulation 259/93. (Of course, on the other hand, trade, will be severely hampered.)

Moreover, given the fact that Regions having responsibility for waste management will also be in a position of appointing Competent Authorities, an additional administrative question is raised. It is rare that the proper Regional infrastructure exists in each of the Regions throughout the European Union which may appoint such Competent Authorities.

If this administrative situation is not solved quickly, it could lead at worst to failure of the entire system or, at a minimum, to the need to store a large number of wastes prior to disposal or recovery, pending clearance. Such storage may result in more environmental, health, and safety problems than the new requirements in the Regulation will solve.

Other administrative concerns include the fact that on the eve of implementation of the Regulation, the standard Consignment Note to be drafted by the Commission was not yet available; the list of competent authorities to be designated by Member States was also not available (indeed, most of the Member States had not even submitted their Competent Authority designations to the Commission); the list of customs offices called for had not yet been published; and the list of wastes on the OECD Green List that will be subject to specific controls in certain Member States was not available, nor was

information on which third countries have bilateral agreements with which Member States or the EU authorizing such trade.

Thus, according to one industry observer, "chaos" will result as companies attempt to comply with the terms of the Regulation, with clearly inadequate and inconsistent administrative structures and procedures in place.

The Commission Staff, while admitting certain transitional administrative problems, does not appear to believe that all of these concerns are fully justified, and international environmental organizations believe that the administrative and compliance concerns of industry are excessive. Reports that illegal traffic in toxic waste, particularly in a West-to-East direction in Europe and to Asian countries, is increasing have led to growing environmental group pressure to strengthen EC legislation even further on this subject. Greenpeace, in particular, is reportedly concerned with increased shipments to Asian countries, as markets in Africa and in Central and Latin America become increasingly difficult to enter, and with reports of mislabeling waste shipments as bound for recycling or recovery facilities, when, in fact, they are being sent to developing countries for disposal.

4.3.3.4. Trade and Competition Issues

Since broad disparities exist among EU Member States on the administrative structures and procedures to implement Regulation 259/93 and definitional and liability disputes continue, competitive differences will arise state-to-state in the EU. In addition, possible uses and abuses of the proximity and self-sufficiency principles by Competent Authorities could give rise not only to political problems, but also to major anticompetitive ones as well.

Although disposal of waste at sites as close as possible to the point of generation is generally preferable, in some circumstances moving waste over greater distances to ensure its proper disposal may be desirable. Moreover, many companies in Europe have one or a limited number of waste disposal or recycling sites to ensure the proper disposal or recovery of their company's waste throughout the EU. Sending waste to these sites to be disposed of will involve movement, possibly over considerable distances, from one site to another and perhaps across national borders in the EU. This growing tendency for large, usually multinational, companies to be as self-sufficient as possible in the integrated management of their own waste should be encouraged rather than penalized by possibly inappropriate application of the proximity principle.

How the growing number of contractual arrangements involving manufacturers of products taking back contaminated products or packaging from customers (under a life-cycle philosophy) will be merged with the requirements of Regulation 259/93 is also unclear. Therefore, under this new Regulation, industry could well face disruption of its waste disposal and recovery programs, delays in operations, and the need to store waste at significant cost and potential environmental risk, pending administrative resolution of these questions.

In addition, some would argue that it is unwise for the EU, given the current economic situation in particular, to adopt more stringent legislation on this subject than its major trading partners have and than is required by its international commitments.

The Parties to the Basel Convention agreed on March 25, 1994, to adopt the EU Council Common Position to amend the Basel Convention to impose additional restrictions on exports of hazardous waste to developing countries (potentially non-OECD states), for disposal immediately and for recycling or recovery as of December 31, 1997. As a result, at the Second Conference of the Parties to the Basel Convention (Basel COP 2) recently held in Geneva, the Basel signatory countries agreed, in Decision II/12, to ban trade of hazardous waste between OECD and non-OECD countries. The U.S. Government and U.S. industry oppose this action and estimate that such a ban on trading waste for recycling between OECD countries and non-OECD (developing) countries could cost the United States about $\$2.2\times10^9$ a year in commodity trade.

A major indusry sector affected by this ban would be the scrap metal industry. In addition, many non-OECD countries are desperate for raw materials to fuel their economies and may, in response, redefine what is considered a Basel waste in order to circumvent the Treaty.

In the European Union, Greenpeace has pressured the European Commission immediately to

bring it into conformance with these Basel Convention commitments. The Commission, on the other hand, does not believe it is necessary to modify the Regulation and certainly not at this time.

Such a ban on hazardous waste shipments between OECD and non-OECD countries, especially for recycling or recovery, would arguably not be compatible with the GATT. In addition, if the hazardous waste definition is overly broad, valuable goods not usually considered waste – for example, chemical byproducts, secondary raw materials, and used electronic goods that constitute legitimate trade between the EU and non-OECD countries – would be blocked. Again, all of these issues and the differing ways in which the EU and its trading partners handle them will likely result in competitive disadvantages for European industry vis-à-vis its non-EU competitors.

4.4. Conclusion

With its Regulation 259/93, the European Community has undertaken an ambitious regulatory program in a much needed area of harmonized EC legislation, with laudable environmental protection goals. However, the scope and complexity of the Regulation, without adequate administrative implementation procedures in place at the EC level and in the Member States, will give rise to significant legal, trade and competition, and administrative compliance problems for European industry. Moreover, the undesirable inconsistencies on this subject among EU Member States are likely to continue to exist in the application and enforcement of this Regulation. In addition, despite ECJ determinations to the contrary, Regulation 259/93 is primarily a free movement of goods/Internal Market measure, not an environmental one. Wastes, especially waste for recovery, should be treated as "goods" under the free movement provisions of the Treaty of Rome. Failure to do so for intra-Community movements of waste violates the letter and spirit of the Treaty of Rome, as amended – without providing additional harmonized environmental protection.

Finally, inconsistent ratifications and implementation of Basel Convention and OECD commitments by the EU and its trading partners will further complicate the competitive problems facing European industry. Recent Basel Convention amendments on this subject, especially with respect to shipments of waste for recovery, arguably violate GATT rules. It will be interesting to see whether, and how, this issue will be resolved in the GATT's – WTO's new Trade and Environment Programme or perhaps in a new GATT "Green Round."

5. The Seveso Directive: An Example of the Interface between Community Law and National Implementation Rules

5.1. Historical Background and Content

Council Directive 82/501/EEC of June 24, 1982 on the major accident hazards of certain industrial activities owes its existence to a number of industrial accidents. Subsequent to accidents in Flixborough in 1974 (United Kingdom), Beek (The Netherlands) in 1975, and in particular at an ICMESA plant in Seveso (Italy) in July 1976, the Commission undertook to draft legislation for the prevention of major industrial accidents, having been encouraged by the intentions of the United Kingdom, The Netherlands, France, and Italy to adopt national legislation in order to improve accident prevention.

The Commission's proposal was submitted to the Council in July 1979, about three years after the Seveso accident. The proposal was largely inspired by measures that existed for nuclear energy installations to avoid nuclear accidents. While the general lines of the proposed Directive were agreed to relatively quickly by the Council, adoption of the Directive was held up because France, in particular, was afraid that information on risks and safety measures to be given to other Member States might create difficulties for the siting and activity of its nuclear installations. Under pressure from the European Parliament, which had from its beginnings been in favor of the adoption of the Directive, and the Benelux countries, a compromise was finally found that enabled the Directive to be adopted in June 1982.

At the end of 1984, a leak of methyl isocyanate from a Union Carbide plant in Bhopal,

India caused the death of more than 2000 persons, and some 20 000 persons were injured. Following that accident, the Commission proposed an amendment to Directive 82/501/EEC, which was adopted in early 1987 (Directive 87/216/EEC). The Parliament, in its opinion on this proposal, had suggested a wide-ranging review of the Directive. However, the accident of Sandoz in Basel in October 1986 and the public concern raised by it necessitated immediate action. The Commission submitted in spring 1988 a proposal for a further amendment that considerably enlarged the existing provisions for accident prevention related to the storage of dangerous substances. That proposal was adopted within six months, a record time, as Directive 88/610/EEC.

The announced general revision of Directive 82/501/EEC was inserted into the Commission's legislative program 1993 but has, as of April 1995, not yet been adopted. Directive 82/501/EEC aims at preventing major accidents and limiting the consequences thereof. Approximating the legislation of the Member States is a means of attaining this objective.

Industrial activity is defined in Article 1 of this Directive. Industrial activity means any operation in an industrial installation listed in Annex I to the Directive that involves one or more dangerous substances and is capable of presenting major accident hazards, as well as storage of dangerous substances under conditions laid down by Annex II of the Directive.

Major accidents are also defined in Article 1: "an occurrence such as a major emission, fire or explosion resulting from uncontrolled developments in the course of an industrial activity, leading to a serious danger to man, immediate or delayed, inside or outside the establishment, and/or to the environment, and involving one or more dangerous substances."

The Commission thought it necessary to publish guidelines for the interpretation of this concept. Directive 82/501/EEC provides for a number of obligations:

1) Manufacturers who process or store certain chemicals have a general duty to prevent major accidents and limit their consequences for humans and the environment (Art. 3 and 4). Should a major accident occur, manufacturers have a duty to report it (Art. 10). The Competent Authorities of Member States have a general duty to organize inspections or other methods of control [Art. 7(2)].
2) Manufacturers, furthermore, have specific duties that apply either when any of 180 dangerous substances are used in quantities above specified threshold levels or when any of 28 dangerous substances are stored. In such cases, the manufacturer must produce and update periodically a safety report (Art. 5) and an on-site emergency plan.
3) The Competent Authorities must ensure that an off-site emergency plan is produced (Art. 5 and 7). They must further ensure that "persons liable to be affected by a major accident" are informed of safety measures and of the correct behavior to adopt in case of accident.

5.2. Implementation Requirements

Member States had to adapt their national legislation to the requirements of the Directive by January 8, 1984. This national legislation and the above mentioned amendments of the Directive phased in gradually. The following shows how three Member States – France, Germany, and Greece – have complied with the requirements under Directive 82/501/EEC.

Situation in France. On August 16, 1982 (i.e., only seven weeks after the adoption of the Directive), France issued an internal circular, by which it drew the attention of the Commissaires de la Republique (the Préfets) to the existence of the Directive and requested that specific care be given to the information requirements contained in its Article 8. It listed the installations that came under the Directive and were, in France, the subject of the legislation on "classified installations" (loi sur les installations classées) of July 19, 1976 and of several decrees issued under that legislation, in particular a decree of September 21, 1977.

The legislation of 1976 provides that all types of installations, listed in a specific register, that might present a risk must obtain an administrative license for operation. The corresponding list includes more than 300 activities and thus goes far beyond the number of installations that are covered by Directive 82/501/EEC.

To fully adapt its existing legislation, in 1987, France adopted legislation on the organization of civil protection, forest protection against fire, and the prevention of major accidents. This legislation requested the establishment of national, regional, or departmental offices for organizing help in cases of accidents and natural or man-made catastrophes. Emergency plans among others were to be prepared by the departmental prefects around certain industrial installations.

These are the essential pieces of French legislation to which workers' safety provisions must be added in order to cover the area of the Directive. What is striking is the fact that the legislation on industrial installations is, to a large extent, umbrella legislation. The major part of the obligations that the Directive places on the individual manufacturer is to be determined by individual administrative decision. Some 500 000 French plants are registered and subject either to a system of declaration or, for some 55 000, to a system of authorization procedure under the legislation of 1976. Most of the elements of Directive 82/501/EEC are found in the 1976 legislation, although this legislation does not seem to cover all elements of Articles 3 and 4.

The requirement for safety reports (risk analysis) was enlarged after adoption of the Directive to cover existing installations. These safety reports under Article 5 of Directive 82/501/EEC refer to some 320 types of installations. On-site emergency plans were, prior to adoption of the Directive, mandatory only for oil industry installations; since the first circulars of 1982 and 1983, they have also been required for installations that come under Article 5 of the Directive. Off-site plans have been requested gradually since 1985, subsequent to legislation adopted that year.

The French system is a clear case of existing means being amended in order to comply better with a Directive that postdates the basic national legislation. Furthermore, the French system gives considerable authority to the departmental, regional, and national administrations, which operate via individual administrative decisions.

Situation in Germany. Germany effected Directive 82/501/EEC and its subsequent amendments by a great number of provisions, under essentially four different categories:

1) Legislation on workers' safety
2) Legislation on chemical substances and preparations
3) Legislation on catastrophes
4) Environmental legislation

Overall, more than 40 pieces of legislation, adopted at the federal or regional level, apply to the subject matter covered by the Directive.

The most relevant provisions to Directive 82/501/EEC are contained in the so-called "Störfallverordnung," the 12th Regulation on the implementation of the Federal Act on Quality Standards (Bundesimmissionsschutzgesetz). For political reasons, Germany thought it necessary to have its national legislation in place when Community legislation on this subject was adopted. This led the German government to submit a proposal for the 12th Regulation on February 20, 1980, while the Commission proposal for Directive 82/501/EEC dates from July 16, 1979. In 1980, the 12th Regulation was adopted in Germany, while the Community Directive was politically agreed to, though not yet formally adopted. The same coincidence occurred after the Sandoz accident in 1986, when both the German government and the Commission submitted proposals. This time the Community acted more quickly; Directive 88/610/EEC was adopted in 1988, while the German amendment was finally adopted in 1991.

The multiplicity of legal texts makes it difficult to identify discrepancies between the 12th Regulation and Directive 82/501/EEC, without being confronted with the objection that other legal provisions explicitly or implicitly cover the aspect in question. The text of the German 12th Regulation is more precise than that of the French legislation; it gives greater legal certainty to industrial installations and less discretion to the administration.

The manufacturers' general obligations are listed specifically, as well as the obligation to establish an on-site emergency plan and a safety analysis. The obligation to inform persons outside the plant has been placed on manufacturers. Off-site measures are to be agreed to with the competent regional or federal authorities. Generally, the threshold levels in German legislation are more stringent than those in the Directive. Also, the list of substances that make the pro-

visions applicable is longer than that of Directive 82/501/EEC.

Situation in Greece. Greece is a Member State that, at the time of its accession to the Community in 1981, had relatively little legislation on the environment. Accident prevention measures for installations were a rather new item, and the Greek administration was not really accustomed to monitor manufacturers' behavior with regard to safety. These rather sketchy lines might help explain why national measures to transpose the amendment of Directive 82/501/EEC took several years. A similar attitude is to be observed regarding the amendment made by Directive 88/610/EEC: only in 1993 after the Commission had filed an application to the European Court of Justice for noncommunication of national implementation measures, Greece transformed the requirements of Directive 88/610/EEC into national law.

The national legislation reproduces the requirements of Directive 82/501/EEC and its amendments correctly. However, the responsibility of monitoring the legislation is given to no less than four bodies [environmental and industrial ministries, prefects at local – regional level, and a Coordinating Interministerial Committee (CIC)]. These rather dispersed responsibilities might have contributed to certain doubts being raised about effective application of the legislation. Indeed, several accidents suggest that effective application, safety analysis, and on-site or off-site emergency plans have not been made for all installations that come under the Directive, nor is regular inspection always made. One reason for this situation is that the different central and local – regional administrations did not receive any supplementary financial or human resources, when the new monitoring tasks were assigned to them in 1988. Thus, the administration does not act as counterpart interlocutor to manufacturers. Since the requirement of informing the public of measures to be taken in case of accident has been placed on prefects, a manufacturer does not incur too serious risks regarding compliance with the Directive's requirements.

5.3. Conclusions

If one looks horizontally at Directive 82/501/EEC and its implementation, a number of observations can be made:

1) The Directive owes its existence and its tightening-up to industrial accidents and public concern; these accidents made possible the adoption of preventive provisions that had not been acceptable at the national or Community level prior to the accidents.
2) Of the three Member States considered, France undoubtedly gives the greatest discretion to the administration and Germany the greatest legal certainty to manufacturers.
3) Effective application of the requirements of the Directive requires flexible cooperation between manufacturers and administration regarding inspection, monitoring, safety analysis, and risk assessment. The administration itself needs to be trained and experienced to be able to contribute to accident prevention without unduly hampering manufacturers' activity. The absence of a trained, effective, and active administration that effectively monitors the practical application seems to be the greatest handicap in Greece.
4) The Directive is not entirely clear on the question of who has to inform the public on safety measures and on behavior in case of accident (Art. 8) – the administration or the manufacturer. This sometimes leads to practical difficulties. Furthermore, if this kind of information is too detailed, it might provoke negative reactions among the population concerned.
5) The cost of prevention might be significant, while the benefits – the absence of major industrial accidents – are very difficult to estimate. Both France and Germany had, prior to adoption of the Directive, taken a number of steps to prevent major accidents, although these measures focused more on human health than on environmental protection.
6) It is not clear under the Directive whose task it is to set up the off-site emergency plan, to ensure its consistency with the on-site emergency plan, and to manage off-site emergency operations. Obviously, the manufacturer is not capable of providing for all details of the off-site plan such as blocking roads or

evacuating the population. Therefore, active cooperation by the administration is necessary, not only in case of accident, but also to learn about cooperative mechanisms and gain experience for any accidental event.

7) French administration has a tendency to ask for measures to prevent accidents in the worst possible scenario, while German administration normally is satisfied with the degree of accident prevention that is reached by using the best available technology.
8) German administration seems to attach limited importance to the question of siting of industries, whereas this aspect plays an increasing role in the French administration's approach to accident prevention.
9) Safety reports play an essential role among all measures required by the Directive. They are considered a means to obtain more precise information on installations, to identify their accident potential, and to prepare preventive measures more adequately. However, which role the administration has to play in this context is not made clear in the Directive. The differences among Member States seem to be important. The administration in Greece seems to be easily satisfied with the safety reports submitted. In France, the authorities examine the safety reports and sometimes require other preventive measures, but never "accept" the report, thus leading to a kind of uncertainty by manufacturers. It might be useful to systematically check, as German administration does, the reports' completeness, correctness, and their effective monitoring and updating.

The hope is that further amendments of the Directive will not be the result of new industrial accidents.

6. U.S. and European Environmental Legislation

6.1. Introduction

This Chapter discusses the nature and role of environmental Regulation, particularly as it applies to the chemical industry. It makes no attempt to summarize the vast and rapidly evolving body of current U.S. and EC environmental legislation. Other sources can be found for this (see, e.g., [68], [69]). The environmental legal provisions applicable to all phases of the chemical industry are now so extensive, detailed, and complex that they cannot be treated exhaustively under a single keyword of Ullmann's.

Rather, the attempt here is to step back from the system and compare briefly the style and context found in the world's two major centers of regulatory activity, the United States, and Europe, to note some of the key features of the legislation in both systems; and to comment briefly on what may lie ahead.

6.2. The Environmental Regulatory System [70]

The United States and Western Europe have had significant environmental laws on the books since the early 1970s. The United States has erected an elaborate edifice of Regulations. At the EC level and in many European countries (Germany being a noteworthy exception), however, a great deal has not happened until recently. Over the past several years, the European Community and its Member States have been generating a flow of environmental initiatives of ever-increasing importance. Now developing in Europe is an extensive framework of environmental regulatory and liability law (see Chaps. 3, 4) that presents business operating in Europe with many of the same kinds of risks found in the United States. The ways these laws are developed in the European Community and in the United States differ fundamentally.

6.3. Methods of Lawmaking in the United States and the European Community

United States. In the United States, the law and lawyers have been central to the development of environmental policy, and highly structured efforts at the federal level have led the way. U.S. Regulation relies heavily on generic, federal administrative rule making to achieve specificity and uniformity, and to gather the technical, scientific, and economic data that form the

premise for public decision making. Administrative rule making proceedings provide public, formal, and structured opportunities for citizens and industry to participate in the development of Regulation through comments, public hearings, and sometimes judicial challenges to rules. The "political" aspects of the U.S. environmental regulatory process take the form of lobbying directed at the U.S. Congress, as well as less formal efforts to lobby the administrative agencies that establish, implement, and enforce Regulations.

In short, in the United States, contending interests use legal processes in the judicial arena and before administrative agencies to influence the formulation and execution of policy. This is particularly true of environmental groups who, with some frequency, use citizen suit provisions in federal environmental legislation as a means of influencing environmental policy.

The result of this dynamic, contentious law and rule making process is a highly articulated, but often inflexible, regulatory system, i.e., a regulatory system that is at times too rigid, complex, and confusing.

EC Regulation (see also Chaps. [**?**]). Regulation in Europe, on the other hand, has traditionally been regarded as "technical" or "political," rather than "legal" in nature, although this attitude appears to be changing. European industry, as a whole, has not in the past looked to legal counsel to assist it in handling environmental matters, but has relied primarily on its technical staff, who often operate through national and European-wide trade associations. The EC regulatory process, furthermore, is largely nonadversarial and is the result of a slow, nonpublic, lawmaking structure designed to achieve political consensus among the Member States. A close industry – government relationship exists. Industry operates through contacts with national authorities; through "expert" advisory committees at the Commission of the European Community; and through lobbying of the Commission, Parliament, and COREPER (the permanent representation of Member States, which assists the Council on day-to-day matters). Proposed Directives are generally made publicly available and are commented on by Parliamentary committees, but until recently, this was not required at the early stages. This situation has been changed, at least in theory, in 1992 – 1993 with the adoption of Council and Commission Resolutions calling for early consultation of interested bodies, including industry associations. No structured open administrative process for promulgating Directives or Regulations exists, however, such as the U.S. notice and comment rule making process.

Implementation of EC Directives is left to the authorities of individual Member States. The degree to which Directives are effectively implemented varies widely from country to country. While some Member States do not give full effect to Directives until long after adoption, other states adopt even stricter measures than those existing at the Community level. For example, Denmark, The Netherlands, and Germany have well-developed national environmental policies. Ireland, Greece, Portugal, Spain, and to some extent, Italy, are in earlier stages of development. Belgium, France, and the United Kingdom are somewhere in the middle, although they have had environmental policies for many years. British law is now developing especially rapidly. As a result of the wide disparity in Member State national environmental laws, chemical companies operating in Europe must be familiar with both Community and national environmental legislation in order to minimize the risk of unexpected environmental Regulation or liability.

6.4. U.S. and European Environmental Laws

Environmental law, to date, has progressed chiefly in two broad streams – one regulating the manufacturing process and the other regulating the products themselves (→ Chemical Products: Safety Regulations). A third stream of natural resource law regulates extraction of the oil, gas, coal, and various minerals that provide the raw material for the chemical manufacturing process. (A number of minor subjects in environmental law deal, for example, with the special protection of certain types of resources, such as wetlands, endangered species, wild and scenic rivers, archaeological sites, and historic preservation. They are not dealt with here since they are less important to and less specific to the chemical industry.) This third broad stream

of natural resource Regulation will be treated in → Raw Materials and Energy. The focus in this section is on chemical process and chemical product Regulation.

Chemical process Regulation encompasses chiefly pollution control Regulation – the classic areas of air emissions, water effluents, and solid and hazardous wastes. It centers on the chemical manufacturing plant, although it typically also applies to all related commercial or industrial facilities (e.g., storage depots, means of transport, and disposal facilities). Generally, the basic tools are construction or operating permits that impose relevant operating constraints, monitoring and reporting requirements, etc. Beyond these standard provisions, however, environmental impact assessment laws, accident planning laws, and public information laws have also been developed, sometimes implemented in permits or the permit process and sometimes separately.

6.4.1. Environmental Impact Assessment Laws

Both the United States and the EC have environmental impact assessment (EIA) laws [71]. These apply chiefly during the licensing of new chemical or other manufacturing facilities or the major expansion of existing plants. They require a systematic, detailed, and written analysis of the likely environmental impacts of the proposed project. This analysis is designed to force both chemical industry management and government regulators to consider environmental factors in their project decision making. In both the United States and the EC, however, the EIA laws themselves mandate no particular result. Rather, they are procedural laws premised on the assumption that a better decision-making process leads to better decisions. U.S. law goes beyond EC law in many ways. It requires consideration of all reasonable alternatives to the project, and has more detailed guidance and "teeth" than its EC counterpart.

6.4.2. Accident Planning and Public Information Laws

The United States and the EC likewise have accident planning and public information laws of great significance for the chemical industry. The EC developed broad-gauged legislation on this subject earlier than the United States, and most European countries have a more systematic approach to risk assessment and analysis built into the new (and modified) plant licensing process than does the United States to date. The EC law (the Seveso Directive, see Chap. 5) is designed to prevent and limit the consequences of major accidents resulting from industrial operations involving dangerous substances [72].

The corresponding U.S. law, the Emergency Planning and Community Right-to-Know Act, requires (1) emergency planning, (2) emergency release notification, (3) community right-to-know reporting, and (4) toxic chemical release inventory reporting [73]. While the EC does not yet have an analogue to the U.S. toxic chemical release inventory requirements, one is on the drawing board. For many years, the United States has also had separate oil spill legislation requiring the well-known Spill Prevention, Control and Countermeasure (SPCC) plans [74] and has much better developed legislation on aboveground and belowground storage tank Regulation than either the EC or most European countries (Germany being an exception in this regard).

6.4.3. Air and Water Pollution Legislation

The air and water pollution legislation in both the United States and the EC is extensive [75]. In both cases, the legislation uses "best-technology"-type substantive emission and effluent standards (emission limits in German terms) as well as case-specific emission and effluent limits to be set at levels necessary to attain air and water quality requirements (the latter called immission standards in German terms).

U.S. water pollution legislation has for years built its control program around a comprehensive permit system, and U.S. air pollution legislation is now adopting the same technique. The EC legislation has had no comprehensive permit system requirements to date, although the Commission is now developing a multimedia permit system modeled after the British Integrated Pollution Control system. The U.S. air and water legislation has regulated new plants

more stringently than existing sources through technology-based new source performance standards for industry categories. The legislation has evolved industry-specific technology-based limits for existing sources on the water side and is now moving to do likewise on the air side, and has developed complex antidegradation requirements (in effect, special limits on degradation of an air or water resource that meets existing ambient requirements). The EC legislation has tended, in practice, chiefly to apply technology-based limits for new sources in a few large industrial categories, and the pervasive air and water quality-based Regulation of existing sources called for by EC legislation has never been put in place. Indeed, not even the air and water quality monitoring systems necessary to implement such ambient-based Regulation have been developed. The Commission is still struggling to come up with a politically and administratively feasible vehicle for setting air and water technology-based limits for the industry, such as are pervasive in the United States and in Germany. Antidegradation requirements, to the extent theoretically present under EC law, have been largely ignored.

In both the United States and the EC, efforts are now being made to move beyond Regulation of the few parameters dealt with in both the air and the water context in the early years and to tackle the difficult and complex job of effectively regulating a multitude of toxic pollutants.

6.4.4. Solid and Hazardous Waste Regulation

U.S. Regulations. In the field of solid and hazardous waste Regulation, the United States has for years had a much more effective regulatory system in place for hazardous waste than the EC (although the German waste regulatory system is comprehensive, except for a loophole in the case of "recyclable" wastes, now to be closed by the new German Eco-Cycle Waste Law of 1994) [76]. The U.S. cradle-to-grave regulatory system uses registration requirements, permits, and transport manifests to regulate virtually all aspects of the generation, storage, transport, treatment, and disposal of a broad range of hazardous wastes (including many destined for recycling), under an extremely complex set of rules and both written and unwritten regulatory practices. All types of treatment, storage, and disposal facilities must meet specific design and operating performance standards, including statutory minimum technology and groundwater monitoring requirements and a prohibition on the land disposal of untreated hazardous wastes. The U.S. system has complex rules for mixtures of wastes; for wastes derived from other wastes; and for distinguishing wastes from products, coproducts, byproducts, chemical intermediates, and secondary raw materials. It regulates some wastes destined for recycle or reuse and does not regulate others. Despite all this hazardous waste Regulation, however, the U.S. system has virtually no comprehensive or systematic Regulation of solid waste at the national level, this area being left almost entirely to state and local governments.

EC Regulations (see Section 4.3). The EC waste management framework is more coherent, but less effective, than that in the United States. The European system is built on a basic framework Directive that deals with all forms of waste and is supplemented by a more specific Directive dealing with hazardous waste [77]. The entire system is now in flux (see Section 4.3).

Further, the European waste regulatory system has depended, from the outset, on Regulation of the *shipment of waste* (see Section 4.3.1). Both the United States and the EC countries have Regulations governing how hazardous materials must be transported, but EC waste shipment Regulation governs whether hazardous waste can be shipped across national borders at all, and under what conditions. As early as 1984, the Directive on Transfrontier Shipments of Hazardous Wastes regulated hazardous waste shipments across Member State borders and into and out of the EC by creating prior notification, manifesting, and packaging requirements [78]. More recently, the community has adopted a new Regulation on Shipment of Waste that implements the Basel Convention in Europe (the Basel Convention governs shipment of hazardous waste on an international scale) and that imposes more stringent requirements (including prior authorization in some cases) on the shipment of all forms of waste, both hazardous and normal, across Member State borders and into or out of the EC (see Section 4.3.1). Shipments of waste

for recovery operations would, depending on how they were listed in three categories (Red, Amber, and Green; see Section 4.3.1) on lists prepared by the "Committee Procedure," be (1) largely excluded from Regulation (green), (2) subject to a prior notification regime (amber), or (3) subject to a prior authorization regime (red; waste not listed would be subject to the authorization system). This Regulation could balkanize the EC on waste matters, with local authorities lodging objections motivated by protectionism of local disposal or recovery facilities and NIMBY-ism. Chemical facilities may be faced with disruption of their waste disposal and recovery arrangements, and those dependent on off-site waste disposal or recovery (and having only limited on-site waste storage capacity) may find their operations at risk of interruption.

To implement the EC's Waste and Hazardous Waste Directives as recently amended, the Commission has drawn up a comprehensive list of solid and hazardous wastes (the European Waste Catalogue). A separate list has been adopted by the Council, which will be critical to EC waste legislation because it will determine the threshold question, for particular wastes, of whether they must be regulated as "solid" or as "hazardous" (see Section 4.3.3). The Commission is also having great difficulty establishing and implementing the definition of "waste" found in relevant Directives.

U.S. Superfund and EC Packaging Legislation. Two idiosyncratic areas of waste Regulation remain to be discussed – one in the United States and one in the EC. In the United States *Superfund legislation* uses government-funded cleanup backed up by a civil liability scheme to deal with soil and groundwater contamination [79]. Originally designed for old dump sites, this broad-reaching legislation extends in fact to all instances of such contamination, both old and new and both on-site at chemical manufacturing facilities and off-site. The government-funded cleanup process has been slow and has been required by Congress to use extremely stringent cleanup levels. The liability regime imposes retroactive, joint and several, strict liability regarding site cleanup liability and responsibility for natural resources. This liability is imposed on virtually everyone connected with the contaminated site since its contamination, including lenders in some cases. The primary Superfund program has been widely criticized and drives broad secondary efforts of private remediation at sites where the potentially responsible parties hope to avoid becoming entangled in the main cleanup and liability program. The European Commission has been considering legislation to deal with soil and groundwater contamination in Europe, and the Council of Europe has adopted a convention on this subject (see Chap. 3).

The second piece of idiosyncratic legislation is the effort by the EC and a number of Member States to regulate one form of solid waste, *packaging*, through product take-back (or advance collection, sorting, recycle, or disposal fees) and thus to develop a new paradigm for regulating all forms of solid waste . The Commission, reacting to the so-called Töpfer Ordinance on packaging waste in Germany and to similar efforts in France and differently structured efforts in other Member States, has proposed a Directive on Packaging and Packaging Waste, which is aimed at eliminating and preventing trade barriers arising from varying national packaging waste initiatives. The essence of this legislation is the ability to impose product charges to force those in the packaging chain, from manufacturer to consumer, to begin to internalize some elements of the costs of collection, sorting, recycle, or disposal of solid waste. The German system achieves the same end by imposing on the commercial parts of the packaging chain a legal "product take-back" obligation. By forcing internalization of some of the costs of the end-of-life disposition of products, the scheme aims at correcting market conditions so as to favor recycling, while letting the market rather than direct Regulation sort out how much recycling is warranted and in which cases. Particularly at the EC level, however, extensive direct regulatory measures, which may well not be environmentally wise or economically efficient, are also being considered.

6.4.5. Regulations on Chemical Products

EC Regulations. Environmental legislation regarding chemical products was one of the first areas pursued by the European Community, although initially its motivations had more to do

with the Common Market than with environmental protection. The first major piece of chemical legislation was adopted in 1967, and established a common Community system for the classification, packaging and labeling of dangerous chemical substances [80]. This basic Directive was modified in 1979 by the so-called Sixth Amendment, which established a premarketing clearance requirement [81]. Under this amendment, companies marketing new "dangerous substances" are required to submit the new chemical substance to a prior notification procedure that involves testing the substance for toxicity and eco-toxicity and preparing technical dossiers to provide information on the substance's characteristics (see Section 2.2). In 1988, the Community adopted similar requirements for dangerous preparations (i.e., mixtures of dangerous substances) [82].

The Commission has also recently adopted material safety data sheet (MSDS) rules and has extended its Regulation to include the marketing and use of certain dangerous substances and preparations, as well as enacting Directives in the field of biotechnology designed to control the handling and release of genetically modified organisms. The Commission is also moving to impose on manufacturers and importers of existing chemical substances some significant data reporting obligations for assessment of their risk characteristics.

U.S. Regulations. In the United States, chemical product Regulation on a comprehensive basis began with the Toxic Substances Control Act in 1976 [83]. That Act places on manufacturers the responsibility of providing data on the health and environmental effect of chemical substances and mixtures and gives the Environmental Protection Agency comprehensive authority to regulate the manufacture, use, distribution in commerce, and disposal of chemical substances. The central regulatory mechanism is the requirement for premanufacture review of new chemical substances prior to their commercial production and introduction to the marketplace. The Environmental Protection Agency also has authority to require testing of chemicals, although no requirement for a "base level" of tests exists as a precondition to premanufacture review as in the Sixth Amendment to the EC Regulation.

Regulation of environmental harms from chemicals in the workplace takes place in the United States under the Occupational Safety Health Act. Under that act, the Hazard Communication Standard requires that employees be informed about the potential chemical exposures involved in their work and be trained to deal with them [84]. Chemical manufacturers and importers are required to evaluate the hazards of the chemicals they produce or import, and to use MSDS to transmit this information to their own employees and to employers to whom they ship the chemicals. Further, chemicals shipped must contain labels on the containers with similar information.

Beyond these core areas, both the U.S. and the European systems regulate use of polychlorinated biphenyls, asbestos, and agricultural chemicals. Further, hazardous chemicals are regulated to varying degrees and in varying ways in consumer products, foods, drugs, and other end uses such as cosmetics and medical devices as well.

6.5. Some Contrasts in U.S. and EC Environmental Legislation [70]

For obvious constitutional and political reasons, the scope, specificity, and rigor of EC legislation do not equal those of U.S. federal legislation.

6.5.1. Regulatory Gaps

Important regulatory gaps exist in the EC (e.g., on wetlands, underground storage tanks, and until recently, municipal sewage), along with weaknesses (e.g., Member State ability to determine, on a relatively subjective basis, the applicability of certain EC Directives on fish protection and bathing water). Nonetheless, in some areas, EC provisions or proposals go beyond present U.S. practices or requirements (e.g., eco-labeling, eco-auditing, packaging waste, and economic and fiscal measures such as a carbon or fuel tax).

6.5.2. Implementation of Legislation

Implementation of the EC Directives is spotty and frequently ineffective. Directives,

particularly the early ones, tend to be general policy statements, with little of the detailed standards and permit requirements of their U.S. counterparts. For example, the European Community as yet has no specific standards for surface impoundments (e.g., pits, ponds, lagoons), underground tanks or pipes, waste piles, and various forms of waste treatment. Where Member State implementation takes place, standards and permit conditions are often negotiated on a case-by-case basis, and systematic monitoring and reporting obligations are not always imposed.

United States. In the United States, the implementation of legislation at the state level is reasonably well assured by U.S. federal legislation through a series of devices lacking in EC legislation. First, a well-staffed, trained, and funded agency (the EPA) can be found at the federal level in the United States. Also available is a great deal of public, comparable monitoring data and other information, as well as effective freedom-of-information legislation at the federal and state levels. Second, the EPA may as a formal matter withdraw a state's right to implement many of the federal regulatory programs if it judges the proposed implementation to be inadequate. The EPA also normally has direct prior approval authority over state-implemented Regulations, standards, and individual permits before those measures can go into effect under federal law (although they can and do sometimes go into effect under state law without regard to EPA approval at the federal level). In the absence of an EPA-approved state implementation program or Regulations, standards, or permits, the EPA is frequently required to promulgate directly applicable federal provisions. Should it fail to supervise state implementation where it has a mandatory duty to do so, it may be sued in federal court by citizens and environmental groups and forced to act. Lastly, the EPA has frequently threatened to withhold federal funding on which the state programs depend if state implementation is deemed inadequate.

6.5.3. Enforcement of Legislation

The enforcement of EC legislation is perhaps the weakest element of the EC regulatory framework. All the European Community can really do is insist that Member States enact legislation (i.e., transpose EC legislation into national law). The European Court of Justice has new power to impose penalties on Member States for failing to implement EC environmental law, but it remains to be seen how effective this tool will prove. An enforceable obligation on the part of Member States to undertake effective, concrete implementation through more specific regulatory standards and requirements, comprehensive permit or approval systems, and an adequately staffed and trained bureaucracy with sufficient funding and legal authority is generally lacking in many countries. Furthermore, the European Environment Agency, which is only just getting started has only a data collection and dissemination function. It does not, for the time being, have enforcement powers.

Enforcement in the United States is vigorous and takes a number of forms. Nearly all of the major U.S. environmental regulatory statutes require some form of publicly available self-monitoring and reporting. The system thereby automatically highlights lapses in compliance and the need for enforcement. When the EPA deems state enforcement inadequate, it normally has the authority at any time to override the state's failure to enforce and to issue an administrative order or, in some cases, to assess civil penalties on an administrative basis. In either case, the EPA may enforce its action in federal court or take the violator directly into federal court for injunctive relief and civil or criminal penalties. Should the EPA fail to do so, citizens and environmental groups can themselves normally take the violators into federal court.

Further Development in the EC. The EC institutions currently have none of these tools at their disposal. At the level of enforcement of specific standards, requirements, or permit conditions against an individual regulated facility, the Community plays virtually no role. Such enforcement is left up to the Member States. Enforcement is difficult, even when attempted, since self-monitoring and reporting obligations have not always been imposed either by Regulation or by permit conditions. Government failure to prosecute generally cannot effectively be

challenged except through publicity and the political process.

The Commission is now engaged in a series of moves to surmount the difficulties it has encountered in trying to develop an effective "command-and-control" EC regulatory system. It is considering the use of fiscal and economic measures instead of administratively driven control requirements. It is trying to make greater use of directly applicable Regulations in the place of Directives that must be implemented by Member States; and in any event, EC legislation, overall, is becoming more specific, thereby providing the detail necessary for ensuring the consistent implementation that has been absent in earlier legislation. The Commission is drafting an Integrated Pollution Control Directive, modeled on British legislation, that would impose comprehensive permitting requirements covering all environmental media, i.e., air, water, soil, groundwater (but, initially, applying only to a restricted list of larger chemical, metallurgical, and paper plants). This Directive would impose substantive and management requirements as permit conditions and would implement on a case-by-case basis the existing media-specific air and water quality legislative requirements. The Commission has also adopted an eco-audit Regulation that provides a (presently "voluntary") comprehensive, universal system that is a partial, periodic substitute for the self-monitoring and reporting provisions that are lacking in existing Directives. These eco-audits would have to be verified by independent outside auditors, with public disclosure of certain information. The likely result of these eco-audits will be public and political pressure for more effective standard setting, implementation, and enforcement.

At a fundamental level, for the first time, the Treaty on Political Union (the Maastricht Treaty), would provide the Court of Justice with limited powers to sanction with penalties those Member States failing to implement EC law. Also, the Court of Justice has been developing the following legal principles to increase the significance of EC law: (1) obligations on national bureaucrats at all levels to apply EC Regulations, even where the national legislature has failed to implement that EC Regulation adequately (i.e., "direct applicabibility"); (2) "direct effect" of provisions in EC Directives that are sufficiently precise and unconditional, even where the national legislatures have failed to implement adequately; and (3) state responsibility for harm to individuals arising from the government's failure to implement EC legislation adequately. The cumulative effect of these developments will be to increase the importance of EC environmental law and to render more likely its effective, if not consistent, implementation and application throughout the European Community.

6.6. Outlook [70]

While the basic framework of U.S. environmental law has been fairly settled (the U.S. Clean Air Act and new initiatives by the first Republican-controlled Congress in 40 years being exceptions), environmental law in Europe is changing rapidly. The past and present roles of European environmental law, of course, indicate that the EC environmental proposals may not necessarily have more than limited importance for business. As is well known, a gap has existed between the rhetoric and the reality of European environmental law. The European Community and many Member States have a good deal of environmental "law" on the books, but much of the EC legislation requires little real action. Moreover, an inability at the EC level and, in some cases, a reluctance at the Member State level to implement and enforce existing environmental law, have been evident. Further, a remarkable lack of comparable data to document many European environmental problems, as well as a lack of data on government actions and enforcement in regard to them, are noticeable.

The politics of the environment appear to be changing, however, As a result of such crises as Seveso, Chernobyl, and Sandoz, and of the palpable, long-neglected environmental problems facing Western and Eastern Europe, public attitudes toward environmental risks in the European Community are evolving quickly. Environmental groups, although perhaps not yet as sophisticated and well funded as their U.S. counterparts, are becoming increasingly well organized and active. Adoption of the EC Directive on Freedom of Information on the Environment and creation of the European Environment Agency, by improving the quantity and quality of publicly available environmental information, will in all likelihood result in heightened public

awareness, increased effectiveness of environmental groups, and consequently, increased political pressure for consistent and effective environmental legislation and enforcement.

7. Environment, Safety, and Chemical Safety in Japan

7.1. Current Situation Concerning Environmental Protection

Since the early 1970s, Japan has made a strong effort to tackle the problem of environmental preservation. Various measures, such as reinforcement of pollution control Regulations and amplification of pollution control facilities have been implemented.

As a result, some serious environmental conditions have been alleviated and the situation has generally improved since the 1980s. Moreover, because the social demand for environmental preservation, particularly in metropolitan areas, tends to be more and more diversified and sophisticated, the Environment Agency is promoting various measures in response to this situation.

In addition, finding solutions to the recent environmental problems that are developing into international and global issues and global climate problems are considered important political subjects by the Japanese government as in other countries. In November 1993 the basic law for environmental pollution control was put in force in response to the result of the UNCED held in June 1992.

7.1.1. Air Pollution Control

Regulatory standards to protect human health (environmental standards) have been set for SO_2, NO_2, CO, photochemical oxidants, and airborne particles based on the Basic Law for Environmental Pollution Control. For Regulation of exhaust gas emission accompanying industrial activities, emission control Regulations are in force for SO_x, NO_x, cadmium and its compounds, Cl_2 and HCl, F_2, HF and SiF_4, lead and its compounds, and exhaust dust. The Regulations are based on the Air Pollution Prevention Law. With regard to SO_x and NO_x, Regulations on total amounts of emissions are also valid within the designated area in the country. In addition to these nationwide uniform standards, special emission standards must be met by newly constructed or expanded facilities in the specified area. In certain areas, additional emission standards have been set by local governments (in municipalities designated by government ordinance).

To meet these standards, industries have taken measures such as desulfurization of exhaust gas [176×10^6 m^3/h (STP) at 1810 facility units], denitration of exhaust gas [142×10^6 m^3/h (STP) at 379 units], development of combustion processes that emit lower amounts of NO_x, absorption of HCl and HF, electrostatic dust separation, etc.

The regulatory system for total NO_x emission control for each industrial installation was introduced into three areas with a high population density, and the system was implemented in Yokohama and in Kawasaki in April 1982, and in Osaka and Tokyo in November 1982.

However, NO_2 concentration in the environment shows an increasing trend, and reinforcing the Regulations on NO_2 mobile emission sources such as automobiles is considered necessary.

In June 1989, the Air Pollution Prevention Law was amended. Fibrous materials such as asbestos that are hazardous to human health have been treated as specific dangerous forms of dusts in this amendment.

7.1.2. Control of Water Pollution

Wastewater Regulation standards were implemented in 1970 based on the Water Pollution Prevention Law. Together with additional standards implemented by the respective local governments (in municipalities designated by government ordinance), water pollution has been controlled with regard to the following items:

1) **Substances Posing a Health Hazard (Toxic Substances).** Concentration limits are set for cadmium and its compounds, cyanides, organic phosphorus compounds, lead and its compounds, chromium(VI) compounds, arsenic and its compounds, mercury, alkylmercury and other mercury

compounds, polychlorinated biphenyls, trichloroethylene, and tetrachloroethylene.

2) **Items Affecting Living Environment.** Limits have been set on pH range, BOD, COD, suspended solids, concentration of oily substances, phenols, copper, zinc, soluble iron, soluble manganese, chromium, fluorine, and a number of *Escherichia coli* colonies.

Industries have promoted various measures such as wastewater treatment and process rationalization. As a result, the environmental standards on toxic substances have been satisfied by 99.9 %, and a general trend of improvement is observed for household effluents. However, in closed water areas such as rivers, inner bays, lakes, and swamps, pollution was still proceeding and eutrophication was advancing. Since the cause of such situations was the insufficent installation of sewage systems for treatment of household wastewater, the Water Pollution Prevention Law was revised.

The Law on Special Measures for Preservation of Water Quality of Lakes and Swamps was enacted in July 1984, and an environmental standard and wastewater discharge control standard for nitrogen and phosphorus concentration were introduced.

The Regulation on the total quantities of contaminants in water was implemented in 1978 for three closed sea areas, namely, Tokyo Bay, Ilse Bay, and Seto Inland Sea, and all-around measures for reduction of the total COD were implemented. In January 1991 the third Regulation for the reduction of total quantities of contaminants was prepared. The countermeasures for water quality control of the closed sea will become more important in the future because tremendous growth of algae resulting from eutrophication will seriously damage fishery by causing red tide.

To counteract groundwater pollution, trichloroethylene and tetrachloroethylene were classified as hazardous substances under the Ordinance for Enforcement of the Water Pollution Prevention Law in April 1989; in June, upon amendment of the Water Pollution Prevention Law, percolation of specific water containing hazardous materials into the groundwater was prohibited. In this connection, the ordinances for reinforcement of the Law related to the Disposal and Cleaning of Wastes were also revised.

7.1.3. Revision of Compensation Systems for Patients with Pollution-Related Diseases

The compensation system for patients suffering from pollution-related diseases was implemented in September 1974, and compensation has been paid, at the cost of polluting parties, to the approved patients in Class no. 1 (directed to the four designated diseases caused by air pollution) and Class no. 2 (directed to diseases caused by water pollution or soil contamination). For Class no. 1, the Central Pollution Study Committee submitted a report in October, 1986 proposing a system that reflects a substantial improvement in environmental pollution.

Based on the above report, a revision bill of the Law on Compensation of Pollution-Related Patients was approved by Parliament. The contents of the revision are (1) all-out cancellation of class I area designation due to the improvement of the environmental situation; (2) continued compensation to approved patients; and (3) promotion of comprehensive environmental hygiene measures (establishment of a fund). As a result, a long-awaited rational revision of this system was implemented in March 1988. By the end of 1993 the number of approved patients was 84 471 and expenses totaled 93.4×10^9 Yen.

7.1.4. Measures for Waste Disposal

Since 1970, the Law on Waste Treatment and Cleaning has been in force, with the two groupings of "Domestic Wastes" and "Industrial Wastes." Section 3 of the law stipulates that an entrepreneur shall be responsible for, e.g., self-accountability, appropriate treatment, discharge reduction, not making products difficult to treat, etc. With respect to industrial waste, the law provides for standards on collection, transportation, and disposal and Regulations concerning the industrial waste treatment industry, industrial wastes treatment facilities, and hazardous industrial wastes.

As far as domestic wastes are concerned, awareness is growing of the need for waste reduction, including recycling of waste. This is due to the fact that the quantities of wastes discharged have been increasing in recent years,

existing incineration and final treatment facilities have reached their maximum capacity, and need exists to utilize limited resources more effectively. The Law Concerning the Utilization of Recycled Resources was published in April 1991. The bill for revision of the Law on Waste Treatment and Cleaning was deliberated by Parliament in September 1991.

7.1.5. Response to Global Environmental Problems

The Law Concerning Protection of Ozone Layers by Regulation of Specified Substances was enforced in Japan in May 1988. The law specifies measures that are to be taken to regulate the manufacture of specific substances, to restrict their discharge, and to rationalize the use of these substances.

In June 1990, the Montreal Protocol was revised to strengthen Regulations by placing a complete ban on the use of certain fluorocarbons by the year 2000 and adding to the list substances such as carbon tetrachloride and 1,1,1-trichloroethane. The related industries in Japan are making efforts to meet these requirements by developing alternative substances for use in place of existing ones.

In August 1990, IPCC of United Nations Environment Program (UNEP)/WHO (the intergovernmental panel regarding climate fluctuation) issued a report about the forecast influences and countermeasures of global warming, which had been studied for three years since 1988. In Japan, corresponding studies have been conducted under the leadership of relevant government authorities. The issue of global warming is also of utmost importance to industries.

It is estimated that ca. 244×10^6 t/a of CO_2 (in terms of C) is discharged in Japan, accounting for 4.3 % of the amount discharged worldwide. Of this amount, about 4.9 % originates from the chemical industry. Since the chemical industry has curtailed energy consumption by about 40 % since the 1980s, little room is available for further energy saving. Thus, reduction of CO_2 discharge appears to be a difficult problem.

7.1.6. Basic Policy of the Japanese Chemical Industry Association about Environment and Safety

The Executive Committee of the International Council of Chemical Associations (ICCA) has set up the ICCA Principles of Responsible Care with the aim of promoting a program for the improvement of voluntary environmental and safety measures.

The Japan Chemical Industry Association concluded that the chemical industry clearly realizes its social responsibility and continues its endeavors to undertake voluntary measures in order to achieve sound growth of the chemical industry at large, at a time when humans are faced with new international problems such as global-scale environmental issues, waste disposal, and the safety of chemical substances. Japan's chemical industry has already made great progress in environmental pollution countermeasures and is at a very advanced level compared with to its U.S. and European counterparts.

7.2. Current Situation Concerning Safety and Fire Prevention Measures

As a result of a series of explosions and fires that occurred in 1973 – 1974 in chemical and oil refinery complexes in Japan, the chemical and related industries have implemented safety and fire prevention measures. Due to such efforts, large-scale explosion accidents in the plants and works have decreased drastically since 1978.

However, the number of accidents is gradually leveling off, and further safety and fire prevention measures should be taken and promoted.

7.2.1. Revision of Fire Service Law

Ignitable and flammable materials are classified as Hazardous Materials based on the Fire Service Law.

On May 24, 1988, the law for partial revision of the Fire Service Law (Law no. 55 of 1988) was promulgated, and in this relation, the revision of the government and ministerial ordinances. The essential part of this revision is the "review of the scope of hazardous materials" to define

the hazardous material more clearly and introduce methods to test whether a substance is hazardous or not. The tests should be performed and judged by the enterprises themselves, following and considering these laws and Regulations.

Another important point is a review of the scope of the term "dangerous articles."

1) The term dangerous article is clearly defined, and judgment of a system by testing is introduced. The test methods and criteria are established by taking into account the definition and international test methods.
2) A designated quantity is determined by government ordinance by taking into account the danger of the articles concerned.
3) Quasi-hazardous materials and special combustible materials are regulated under the category of combustible materials.

The provisions relating to the revision of the scope of dangerous materials in this law were enforced as of May 23, 1990.

7.2.2. Safety Measures for the Transport of Dangerous Goods

For the air and marine shipments involved frequently in international transport, international Regulations have been introduced so that Japanese domestic legislation is consistent with international transport standards.

7.2.2.1. Marine Transport Standards for Hazardous Substances

Breakbulk Transport. The Ministry of Transport provided Rules for the Marine Transport and Storage of Dangerous Goods with respect to the breakbulk transport. The rules were determined with reference to the International Marine Dangerous Goods Code (IMDG Code) set by the International Maritime Organization. The notice of revision incorporating the 25th revision of the IMDG code was enforced in January 1991. With regard to container testing, the test system and UN label indication system have been internationally enforced since January 1991, and the use of qualified containers having UN labels is obligatory for the transport of dangerous goods.

Transportation in Bulk. With regard to the marine transport in bulk of hazardous liquids by chemical tankers and liquid gas tankers, the Rules for the Massive Transport and Storage of Dangerous Substances were amended as of July 1986, and the International Bulk Chemical Code (IBC) and International Gas Carrier Code (IGC) of the IMO were officially adopted.

The amendment of IBC Codes was adopted in March 1989. In response to this amendment, the Ocean Pollution Prevention Law, the Regulations on the Marine Transport and Storage of Dangerous Materials, etc. were revised and enforced in October 1990. In particular, as for the Ocean Pollution Prevention Law, it is not necessary to make prior assessment for pollution classification of goods mixed with pollutants already assessed or that contain pollutants already classified by the International Marine Organization.

7.2.2.2. Standards for Air Transport of Hazardous Cargoes

With respect to air transport, standards for the transport of hazardous cargoes (notification) in Japan are determined on the basis of the Aviaiton Act. These standards are in accordance with the Regulations on hazardous cargoes (International Civil Aviation Convention Annex no. 18) and the technical guidelines of the International Civil Air Organization (ICAO). These standards (notice) were revised on December 20, 1990, and enforced on January 1, 1991. Testing of containers and the use of containers with UN labels have been obligatory since 1991 as in the case of marine transport.

7.2.2.3. Standards for Transportation Containers for Poisonous and Toxic Substances

The Control Act on Poisonous and Toxic Substances stipulates the handling of poisonous and toxic substances.

The Pharmaceutical and Supply Bureau of the Ministry of Health and Welfare issued the standard on transportation containers for poisonous and toxic substances (no. 3; a standard

for small-size transportation containers having an inner volume of 450 L or less). The standard went into effect on October 1, 1991.

This standard is in line with the United Nations Hazardous Substances Experts Committee Recommendation-no.6 Edition from the standpoint of international harmonization. Also on October 1, notice was given of the establishment and revision of standards concerning each of the poisonous and toxic substances with respect to emergency measures in transportation accidents as well as disposal.

7.2.2.4. Safety Measures in the Use of Gases Under High Pressure

Safety Regulations with respect to high-pressure gas are in accordance with the High-Pressure Gas Control Act and governmental ordinances associated therewith.

The Industrial Location and Environmental Protection Bureau of the Ministry of International Trade and Industry has been holding meetings of the High-Pressure Gas Safety Policy Committee since September 1989 to study the best possible way of organizing high-pressure gas safety administration in the future. In June 1991, a report was published, proposing the following:

1) To promote self-security (i.e., self-protection measures and attitude for security)
2) To strengthen safety measures in response to diversification of applications
3) To review import Regulations from the standpoint of internationalization
4) To promote international cooperation in the field of safety
5) To strengthen execution systems by making full use of private-sector inspection organizations
6) To enhance systems supporting voluntary security activities

Since July 1991, the Ministry of International Trade and Industry has been holding meetings of the High-Pressure Gas and Explosives Safety Review Committee to study the future administration of high-pressure gas safety, including revision of the High-Pressure Gas Control Act.

7.3. Present Situation Regarding Safety Measures for Chemical Substances

In Japan, two laws exist for maintaining the safety of chemical substances under the notification system for new chemical substances prior to the manufacture thereof: (1) The Law Concerning Examination and Regulation of Manufacture, etc. of Chemical Substances, which is designed to regulate substances that are hazardous to human health because of contamination of the environment and (2) the system of Investigation of Toxicity of Chemical Substances under the Industrial Safety and Health Law, which is to regulate the concentration of carcinogenic substances in the workplace.

7.3.1. The Law Concerning Examination and Regulation of Manufacture, etc. of Chemical Substances

The Law Concerning Examination and Regulation of Manufacture, etc. of Chemical Substances had been, until its revision in April 1987, implemented effectively for the 14 years since its enforcement in 1973 to regulate PCBs and similar substances.

However, as Regulations became stricter in Europe and the United States, the need arose to coordinate Regulations on chemical substances in various countries and to expand Regulations on harmful chemical substances that are slowly degraded in the environment. The Japanese government then enacted a Law for the Partial Revision of the Law Concerning Examination and Regulation of Manufacture, etc. of Chemical Substances in May 1986 and implemented it in April 1987. The gist of the revised law is as follows:

1) The system of prior examination of new chemical substances was reinforced by demanding that toxicity tests, namely, mutagenicity tests (Ames test, chromosonal aberrations test) and repeated dose tests are to be conducted for 28 days, in addition to the biodegradability and accumulation tests now in force. The tests must be performed, at the time the government is notified of the chemical substances, prior to their manufacture and import.

2) Substances that are difficultly degradable and are suspected to have chronic toxicity are to be termed "Designated Chemical Substances" and must be put under surveillance with respect to their production volume and application after manufacture and import.
3) When such "Designated Chemical Substances" are suspected to be contaminating the environment and be hazardous to human health, the manufacturer or importer will be advised to perform a study on hazards of such substances.
4) If such studies reveal that the substances are hazardous, they are termed "Class II Specified Chemical Substances," and their production volume and handling methods must be regulated.
5) "Specific Chemical Substances" with respect to the old Law Concerning Examination and Regulation of Manufacture, etc. of Chemical Substances are now termed "Class I Specified Chemical Substances," and the same control measures, such as ban on their manufacture in principle and on their use in open systems, are used as in the past.
6) As a result of tests conducted by the government on existing chemical substances (which correspond to a prior examination for new substances), some of them may be termed "Designated Chemical Substances."

7.3.2. Situation Regarding the Enforcement of Law Concerning Examinations and Regulations of Manufacture, etc. of Chemical Substances ("Chemical Substances Law")

Under the old Chemical Substances Law (until March 1987) the reported number of new chemical substances admitted for manufacture and import was 3864; under the new Chemical Substances Law (April 1987 – December 1993), which applies more stringent Regulations, it is 1492.

The designated chemical substances as of the end of September 1993 amounted to 97, including chlorohydrocarbons and organotin compounds. Among them are 135 substances (excluding the 23 substances that were regrouped to the "Class II Specified Chemical Substances") whose manufacture and import quantities must be reported. The 23 specified chemical substances inlcude chlorohydrocarbons (trichloroethylene, tetrachloroethylene, carbon tetrachloride) and organotin compounds (e.g., triphenyl- and tributyltin compounds). Furthermore, safety measures for each substance such as the preparation of proper use manuals and labeling of containers are being taken by individual industry organizations.

As far as existing chemical substances are concerned, the government continues to conduct systematic safety monitoring. The Ministry of International Trade and Industry checked the safety of 970 substances from 1974 through 1993. The result was that 358 substances decomposed in solvents to nonhazardous compounds, 594 substances showed low and 18 substances high accumulation of hazardous compounds upon decomposition. Of these, the nine substances or classes of substances listed below are designated Class I Specified Chemical Substances. In addition, the Ministry of Health and Welfare conducts toxicity testing of each substance.

Polychlorinated biphenyls
Polychlorinated napththalenes
Hexachlorobenzene
Aldrin
Dieldrin
Endrin
DDT
Chlordane
Bis(tributyltin)oxide

More careful handling and discharge, not only of those substances that are regulated specifically but of all chemical substances in open systems, is desired.

7.3.3. International Cooperation on Chemical Substance Regulations

In Japan, the Good Laboratory Practice (GLP) system was introduced in 1986, and the coordination of testing methods with those of OECD and the mutual acceptance of test data were promoted.

Moreover, the OECD started to promote the work of international cooperation for investigating the safety of existing chemical substances.

Specifically, the preparation of data bases (EXICHEM) on the testing status in member countries and joint investigation of chemical products of high production volume are being put in force. Concerning the joint investigation of chemical products with a high production volume, 53 substances were allocated in April 1990 to each country as Phase 1 in accordance with the investigation priority substances (P 1) list. Japan took charge of nine substances and collected data on them. Based on the result of this investigation, tests in 1991 were conducted with respect to characteristics on which no data were available or the data were indefinite. In addition, investigation of about 100 substances (Phases 2 and 3) was initiated toward the end of 1991. In this program Japan is to evaluate data on 24 substances. Furthermore, until the year 2000 about 5000 chemical substances of high production volume including the above figures will be surveyed. Japan will evaluate one-fourth of those substances.

1. Introduction

1.1. Historical Development

A few decades ago, the term "environmental management," not to mention "environmental management system," would have raised eyebrows. Despite the fact that some advanced companies were already behaving quite properly as far as environmental protection was concerned – at least relative to the prevailing standards – the term had not yet been coined, and companies did not have the type of environmental organization considered necessary today.

Nevertheless, environmental considerations had been taken into account, consciously or unconsciously, in the management of chemical industry for a long time: one might quote, for example, a French imperial decree from 1810 controlling "dangerous, noxious and infectious establishments" which could be considered as a precursor to the EC "Seveso" Directive. Closer to the present, the Solvay process for the manufacture of soda ash, which in the second half of the nineteenth century replaced the Leblanc process, brought substantial environmental improvements.

In fact, safety considerations were integrated into industrial management long before the need to protect the environment was recognized. Following dramatic accidents and severe health damage that were common in the early stages of the industrial revolution, governments, supported by a few enlightened industrialists, established the first of many standards for process, product, and human safety. The efforts of certain politicians to protect workers against the effects of white lead, and of Chancellor Bismarck to lay the foundations for accident prevention and social security, are well known examples. Some major companies, such as E.I. du Pont de Nemours, have built their reputations on the basis of very strict safety standards.

But it was not before the 1960s or 1970s that the impact of chemical products and chemical industry on the environment were widely publicized – first in 1962 with Rachel Carson's "Silent Spring," then with the UN Conference in Stockholm in 1972. Since that time, local and national governments as well as intergovernmental organizations, in particular the Organization for Economic Cooperation and Development (OECD) and various United Nations Agencies, have established a number of legislative actions, conventions, or recommendations that have necessarily been integrated into the management of chemical companies.

The concept of "Sustainable Development" was introduced in the 1987 report "Our Common Future" from the UN Commission for Environment and Development, led by G. H. Brundtland [1]. The report recognized the threats imposed on the environment by both increasing population and ongoing industrial development, but it also identified challenges that must be met if such development is to be sustained without compromising the needs of future generations. Industry has an indispensable role to play if these objectives are to be achieved, in particular with respect to energy consumption, food production, and chemicals.

The Brundtland report paved the way to organization of the UN Conference on Environment and Development (UNCED), held in Rio de Janeiro in June 1992 [2]. Whatever can be said about the meager immediate results of the Conference, its products, in particular the "Agenda 21", will have to be taken into consideration by industrial managers. Two chapters of Agenda 21 are of direct relevance to chemical industry, and a United Nations Commission for Sustainable Development (UNCSD) has been set up to implement the Conference's decisions.

The integration of environmental considerations into industrial management is influenced most obviously by the level of development of the country in question: even within the European Community, after more than twenty years of legislative actions to harmonize ("approximate") national legislation, some differences still exist between the behavior of certain companies in different Member States. When one looks at developing countries, the differences are often even greater. Political regimes also have an influence on environmental awareness and requirements: the state of the environment left by the centrally planned economy regimes of the former communist countries clearly shows that free-market economy, democracy, and a high state of development all contribute to superior environmental protection in industrialized or industrializing countries.

1.2. Factors Influencing Companies to Improve Their Environmental Performance

While companies undoubtedly must satisfy first their "bottom line" (profitability), as well as a second crucial one – socio-economic responsibility – they now must satisfy a third one as well, namely environmental responsibility. Several factors are pushing industrial managers to meet this third challenge and to improve the environmental performance of their companies. Some of these are listed below, in an order that might vary depending on a particular manager's personal commitment, the company's culture, the local legal and economic conditions, etc.

Legal Requirements and Regulations. In all industrialized countries, environmental regulations are now being established at an ever increasing pace (Fig. 1), and they are setting ever tighter standards. Although enforcement requirements may differ between countries, no reputable company can afford not to comply with at least national and local regulations.

Figure 1. Evolution of environmental legislation in the European Community (EC)

Environmental Liability. Fears of prosecution triggered by civil or even criminal liability for environmental damage are a strong incentive toward excellence in environmental performance. Some well-known "environmental scandals" have been settled, either between the parties involved or by the courts, at levels that could endanger the financial survival of a company. A matter of especially great concern is "past pollution"; i.e., the ecological damage created by an industrial operation that was complying fully with the legal requirements of some past period. Even if not yet common, criminal liability for environmental damage may soon become a reality, as is already the case for safety failures. Several pieces of legislation (Council of Europe, European Community) based on the concept of "strict" liability will make the matter even more important (see Chap. 4 for more detailed information).

Image. As the public, under the influence of the media and many environmental nongovernmental organizations (NGOs), becomes increasingly aware of the need to protect the environment, companies will need to build public images as "good environmental citizens" if they hope to maintain their licenses to operate. There have already been cases of companies boycotted by consumer organizations in response to some environmental affair. "Eco-labels" or "Green Awards" have become strong elements in marketing strategies, and environmental performance criteria are becoming subject to more and more consideration in relations between suppliers and consumers.

Employees. Employees and unions have traditionally been particularly concerned by labor relations, and especially wages, working conditions, and safety, but they are becoming increasingly interested as well in the environmental performance and reputation of the companies with which they are associated. Some companies have established "Environment Committees" at the shopfloor level paralleling the long-established Safety Committees.

There are also clear indications that a good environmental image helps a company recruit high-quality personnel, especially at the management and executive level.

Finance. It is now recognized by the financial community – shareholders, bankers, insurers – that good environmental performance is an asset, even if in the short term it entails some capital expenditures and increased operating costs. There are more and more cases of corporate annual general meetings of shareholders where questions on environmental performance are debated. Moreover, insurance companies now adjust their premiums according to the environ-

mental reputations of their clients. Some organizations have proposed to their customers – mostly in the financial community – an "eco-rating" of major industrial corporations, similar to financial ratings.

Professional Associations. Industrial associations at the national or international level have no real power over their member companies, but they are nevertheless an effective platform for establishing common principles and guidelines that set a high-level yardstick of environmental performance for all their members.

Ethical Considerations. Some industry leaders are already well-known for their personal commitments to environmental protection, and they manage their companies accordingly. Many other company executives are beginning to transfer to their management activities their personal ethics with respect to the environment.

1.3. Scope of This Contribution

When speaking about environmental management it has become current practice to discuss health-protection and safety-management aspects together with purely ecological matters. This contribution devoted to "environmental management" will therefore include various aspects of health, safety, and environmental (HSE) management. It must be recognized, however, that in some companies these elements are not integrated, and that health protection (H), safety (S), or health protection and safety (H + S), are managed separately from environmental protection (E). Conversely, some companies include quality under the same management structure. Because of their specificity, safety and environmental aspects of transport and distribution are integrated into an HSE management structure by only a few companies.

2. Environmental Management in Chemical Companies

2.1. Preamble

As noted in the previous chapter, the concept of environmental management is relatively new; it has developed without established standards, in a "learning-by-doing" process. It is therefore no wonder that the environmental management structures adopted by individual companies differ significantly according to company size, geographical location, and coverage; the legislative framework of the country(ies) in which they operate; their culture; etc.

What is described below is the typical structure, organization, and content of an environmental management system adopted by a typical large or multinational company with headquarters in one of the industrialized countries. Companies of smaller size or operating under different conditions should adapt it accordingly.

2.2. Environmental Management Systems

Basically, the functioning of a company relies on two systems:

1) An *operational system*, which achieves the basic purposes of the company (e.g., the manufacture of a certain range of products under certain financial and social conditions)
2) A *management system*, which acts on the operational system to help it function and improve

Management systems applied to the various aspects of management are an important key to the long-term success of any company. Fundamentally, such a system necessitates defining a policy, establishing standards and objectives, planning for achievement, and allocating whatever resources are required, as well as documenting, measuring, auditing, and reviewing for improvement. An environmental management system (EMS) is built along this "loop," as represented by Figure 2 (see next page). Its main elements are described below.

2.3. Environmental Policy

Although it must be recognized that establishing and publicizing a policy for HSE matters is not, or at least not yet, a part of the culture of some companies, a clearly stated environmental policy is undoubtedly the foundation of any environmental management system.

Figure 2. The environmental management system (EMS) "loop"

An *environmental policy* can be defined as a public statement of the intentions, principles of action, and objectives that govern the management of a company with respect to the environment. Although the details and extent of such a policy may vary from company to company, the policy itself is generally expressed in a concise statement. Typical elements include:

1) A commitment to conduct the company's activities in a manner that safeguards the environment, the health, and the safety of its personnel, local communities, consumers, and the general public
2) Compliance with environmental legislation, or even an intention to go beyond legislative compliance when appropriate
3) Communication of environmental information to concerned stakeholders within society
4) Information for customers on the nature and safe use of the company's products
5) Environmental education and training of employees and contractors
6) Support for environmental research
7) Access to environmentally sound technologies

A corporate environmental policy is a document approved and endorsed by the highest level of management; the President, Chief Executive Officer (CEO), or Executive Committee. The policy is also made available to the public and communicated to all interested parties, in particular the company's employees, shareholders, and major customers.

2.4. Organization and Structure

To implement a company's environmental policy the necessary human resources must be allocated and organized in such a way that they work with the greatest possible effectiveness, in particular in their relationship with the operating system. Organization implies a structure that identifies areas of responsibility and authority for key personnel.

2.4.1. Typical Organization

Again, the personnel structure of an environmental management system may differ quite considerably from company to company, but a typical organization is that described by Figure 3 (note, however, that in some companies the functions H + S and E are separated). The basic principles are as follows:

Figure 3. Structure of a typical health, safety, and environmental (HSE) organization

The *Board of Directors* is responsible for defining the company's environmental policy. Some companies have established an "HSE Advisory Committee" to assist the Board in this function; members of the Advisory Committee are members of the Board or persons external to the company selected for their interest, competence, or representativity in HSE matters.

The *Managing Director* (President, CEO) is responsible for the adoption and implementation

of the company's environmental policy. His personal involvement should be made clearly visible across the company (in the famous words of DuPont's E. WOOLARD: "as Chief Officer of this company, I am also its Chief Environmentalist" [3]).

A *senior manager* (Vice-President, Director) reporting directly to the President, heads the company's central HSE department. This centralized function is not directly responsible for policy implementation, but ensures the proper working of the various elements of the EMS. It includes specialized activities such as toxicology/ecotoxicology, occupational health, emissions, waste management, environmental audits, product safety, regulatory affairs, etc. Most of the members of the central HSE departments act in an advisory capacity to support the "line" management.

Business units (product divisions, manufacturing companies, geographical areas) are responsible for policy implementation. Here again, HSE directors or coordinators at the level of the division or site function in an advisory capacity.

2.4.2. Staffing of HSE Functions

The number of employees holding a full-time HSE position varies widely, depending on such factors as process and product hazards, local regulations, etc. An approximate range is from 2 to 25 HSE staff members per 1000 employees, with an average around ten.

Allocation of professionals between a central corporate HSE department and the HSE departments in various divisions and sites is again a matter to be decided by the company: Some have large centralized departments, with up to 150 experts competent in all aspects of the corporation; others prefer to decentralize to the greatest extent possible at the level of divisions or sites, maintaining only a light core group with mainly coordinating functions.

Whether the HSE functions should be staffed by generalists or by professionals educated in HSE matters is much debated, especially since the educational system now provides explicit technical or university degrees in HSE disciplines. Equally important are concerns about the possibility of career development for specialists in HSE. Many companies regard an HSE position as a necessary step toward general management; others ensure that HSE specialists have career development opportunities similar to those offered to generalists.

2.4.3. Employee Motivation and Training

As noted previously, employees in business units and operational sites are responsible for the implementation of a company environmental policy. This requires that staff at all levels be clearly aware of their accountability, as well as properly trained and motivated.

Most companies hold employees accountable through evaluation of their individual environmental performance, or at least safety performance, which is more easily measurable. Plant and site managers are often required to set HSE objectives for their specific areas of responsibility, with possible monetary bonuses linked to achieving the goals. Several companies have prize programs with monetary awards or other forms of recognition for environmental improvements.

Training in HSE matters is a key element in the effectiveness of an EMS. Training is especially necessary when a generalist is appointed to an HSE position. Several companies include HSE elements in their training programs for managers at various levels. Training of all employees in HSE matters is more and more considered to be a major priority, even if for the moment only a few companies have implemented such comprehensive programs.

The case of line middle-managers deserves special consideration, because these persons sometimes perceive environmental demands as coming from people outside the plant with little knowledge about what is happening in practice. It is therefore important that senior management demonstrate its commitment to environmental quality, for example, by facilitating a two-way communication channel on HSE matters, allocating the necessary human and financial resources, and properly rewarding positive achievements. Also, programs that include a strong motivation element, such as Responsible Care (see Section 5.4), are helpful in convincing line managers, as well as staff people like sales managers, of their environmental duties.

Another difficult case is that of contractors working on behalf of a company for construction or maintenance work, waste disposal, transport, etc. It is normally part of a company's policy to insist that contractors work under the same HSE standards as the company's own personnel, but accountability, communication lines, training possibilities, etc. are obviously different. The problem requires special attention on the part of all those involved.

2.4.4. Research and Development

Most major chemical companies have R & D programs devoted exclusively to HSE matters and representing some 10 – 25 % of all their R & D expenditures. Environmental R & D topics are linked most obviously to a company's products and processes, and to its HSE priorities and programs.

2.5. Standards, Regulations, Monitoring, and Environmental Programs

A fundamental element of an EMS is a comprehensive register of applicable legislation and company standards. It is against these governmental or company standards that environmental performance will be measured, permitting the necessary programs for correction or improvement to be developed.

2.5.1. Register of Standards

The number and complexity of environmental statutes at the local, national, and international level is constantly increasing. It is the role of a central business unit or individual site HSE functions to determine those that are applicable in the various sectors of the company. It may also happen that, because of gaps in the applicable legislation or difficulties in adapting it to the specialties of a certain activity, a given company is forced to establish its own standards, which would of course go beyond the legislated criteria. In general such standards are established at the highest level of the company, and are applicable to all its sectors.

To ensure proper implementation by line personnel, legislation and company standards may require more detailed guidelines or guidance notes. Such guidelines, generally drafted by professionals in the central HSE department on the basis of their own experience and outside information, provide site managers with key principles that are to be incorporated into local procedures.

Maintaining the currency of all documentation of applicable laws and standards, guidelines, and local procedures, and communicating modifications and additions to the affected personnel, is a difficult task; a written procedure with clear allocation of responsibilities may be necessary.

2.5.2. Measuring Environmental Performance

"You can't manage what you can't measure." Therefore, to measure the effectiveness of an environmental management system, real data are required on the precise effects of the company's activities on the environment and individual people. It is thus necessary to conduct a planned, regular sampling and monitoring program at the various company sites as well as outside the company (e.g., regarding the effects of certain products).

It is generally accepted that the parameters to be monitored should include:

- Point sources and fugitive emission to the atmosphere
- Point sources and fugitive discharges to water or sewers
- Solid and other wastes, particularly hazardous wastes
- Contamination of land
- Use of water, fuels, and energy
- Discharge of thermal energy, noise, odor, and dust
- Effects on specific parts of the environment and ecosystems
- On-site accidents and near-misses
- Personnel injuries
- Transport accidents
- Complaints from community residents
- Complaints from customers related to HSE matters

All these data should be obtained by prescribed or accepted (standardized) measurement techniques and collected in registers established at various levels in the company. Some companies collect only absolute figures, while others combine certain data with appropriate weighting factors into an index or several indices. Such indices may be useful management tools for fixing objectives and demonstrating improvements.

Results of all measurements are communicated to the various interested parties, from plant operators to senior management, at the appropriate frequency and in the relevant form.

2.5.3. Environmental Programs

On the basis of global, long-term targets, set at the highest achievable level (e.g., 50 % reduction in waste generation within the next 10 years), together with data from the register of environmental effects, individual environmental programs are established for the various sites and units of a company. Programs usually cover a one-year period within a multi-year global program.

Proposals for individual programs are checked for feasibility, relevance, and priority, usually by the central HSE department. A proposal for a corporate environmental program is then submitted to senior management, which decides on the proposals to be accepted and allocates the necessary human and financial resources. The corresponding investments are included in the global investment program of the company.

It is not easy to determine the amount of capital investment currently devoted to HSE by chemical companies, in part because there is no established methodology for computing these expenses. Furthermore, while it may be reasonably easy to determine the cost of end-of-pipe equipment, how is one to isolate the environmental component in the cost of a "cleaner," integrated process? Estimates of capital expenditure related to HSE average 10 – 20 % of total capital investment for most companies. Operating expenses for HSE are in a similar range, and these are expected to increase, at least as long as processes intrinsically safe and "clean" are not generalized.

2.6. Environmental Audits

All companies have long been accustomed to having their financial management systems audited by accredited experts. A few decades ago the auditing of safety practices became a current practice for many companies. Only a few are so far familiar with the concept of "environmental auditing," but a trend in this direction is spreading rapidly across industry.

2.6.1. Definition

The International Chamber of Commerce (ICC) has proposed the following definition for an environmental audit [4]: "A management tool comprising a systematic, documented, periodic, and objective evaluation of how well environmental organization, management and equipment are performing with the aim of helping to safeguard the environment by:

1) Facilitating management control of environmental practices
2) Assessing compliance with company policies, which would include meeting regulatory requirements"

Such a definition might appear somewhat narrow when one considers that many corporate policies tend to cover unregulated risks. Indeed, the United States Environmental Protection Agency (EPA) has included such unregulated risks in its definition of environmental auditing.

Environmental audits are therefore a necessary component of a company's environmental management system, permitting a determination of whether or not the system is implemented effectively and is suitable for fulfilling the company's environmental policy.

Given the many activities of a company that have a bearing on the environment, environmental audits may serve various purposes:

Compliance audits verify that an industrial activity meets its legal obligations (permits, emission limits, etc.). They do not differ in principle from inspections by government inspectors.

Health and safety audits are still carried out separately in many companies, even though the tendency now is to integrate them into global environmental audits.

Site audits are the most common type of environmental audits. They are designed to check individual site activities against those elements of a company's environmental policy and management system applicable to the site in question. For large sites, audits may be limited to a single plant or a series of units.

Specific issues may also be the subject of an environmental audit at the corporate or site level, such as waste management, transport and distribution activities, etc.

2.6.2. The AuditPlan

To ensure proper verification of a global environmental management system, auditing of the various facets of a company's activities should be carefully planned.

The central HSE department is generally responsible for establishing an appropriate *audit plan*, which should deal with the following points:

1) Setting priorities
2) Establishing specific areas and activities to be audited and the frequency for auditing each particular site as a function of the nature and risk of its activities as well as conclusions reached in the previous audit; experience shows that a frequency of one to five years covers most situations encountered in the chemical industry
3) Objectives of the various audits
4) Personnel requirements
5) A protocol for conducting the audits
6) Procedures for reporting audit findings

2.6.3. Environmental Auditors

It is generally accepted, even in legislation (see Section 4.4), that environmental audits should be performed either by personnel from within the company (but wherever possible independent of the unit being audited) or people external to the company. A growing number of organizations and consulting companies are offering their expertise for environmental audits, which may be useful when internal expertise or capacity is lacking. Because of the rapid development of this market, great care should be exercised in the selection of an external consultant. Simultaneously with the publication of the ISO 14 001 Standard for Environmental Management Systems, ISO issued in 1996 a series of guidelines for environmental auditing:

– ISO 14 010: General principles on environmental auditing
– ISO 14 011: Audit procedures – Auditing of environmental management systems
– ISO 14 012: Qualification criteria for environmental auditors

A large number of environmental auditors have already been accredited to carry out third party ISO 14 001 audits according to the abovementioned auditing requirements.

In its efforts to make the ISO 9000 and ISO 14 000 series of standards more compatible, ISO decided in 1998 to develop one common auditing standard for quality and environmental management systems, replacing ISO 10 011 and ISO 14 010/14 011/14 012.

Companies may want to carry out environmental audits using their own teams of auditors, supplied either by the central HSE department or drawn from various line activities within the company. It is highly recommended that the auditing requirements expressed in ISO 14 010/14 011/14 012 should be taken into consideration. A typical team includes three to four persons under the recognized authority of a leader. At least two members of the team should be experts in environmental matters, and one or more should be familiar with the particular type of activity to be audited. All members should have the necessary skills to obtain, from observation and interviews, clear, unbiased information on the operation in question without being regarded as "policemen" by the local employees. To facilitate contacts and technical arrangements an employee of the unit subject to audit may be nominated to act as a liaison with the auditing team.

The time required for an environmental audit varies considerably according to the size of the site, the nature of the operation, the cooperation of local personnel, etc. It may range from a few days to several weeks.

2.6.4. AuditMethodology and Process

The detailed actions required to carry out an environmental audit are highly dependent on the type and nature of the activities to be audited, but the following features are common to most audits:

1) Identification of elements of the management system, including instruction manuals, written procedures, communication, and reporting schemes
2) Evaluation of the control system
3) Assessment of strengths and weaknesses of the management system, especially deviations from written procedures and failures in the reporting lines
4) Examination of records of data on controlled or accidental emissions, energy use, complaints, etc.
5) Evaluation of training and motivation of personnel

Auditors collect the necessary information through direct observation and interviews of personnel at the plant, drawn from all levels. Cross-checking of information is a common practice, but care should be exercised to avoid friction with and between employees. Contacts may be facilitated by starting the audit activities with a brief meeting with plant personnel, where the audit objectives, plan, and methods are explained. The full cooperation of local management is in any case required.

Immediately at the conclusion of an audit the leader of the auditing team should present the major findings to the local (plant or site) management. Already at this stage a number of immediate corrections can often be achieved.

2.6.5. AuditReport and Action Program

The final report is drafted by the team leader, and usually checked by the site manager before being sent to senior management (President and/or Board).

A typical report includes three parts:

1) An executive summary of major findings
2) A section on detailed observations, the part most useful to local management for improving the operating procedures
3) A proposal for corrective actions, including capital investment, major equipment modification, or changes to managerial procedures when appropriate

The corrective action program is discussed at senior management level. When approved, in conjunction with an appropriate time scale, it is integrated into the global environmental program of the company.

2.7. Environmental Management Reviews

The suitability and effectiveness of an environmental management system must be assessed at regular intervals. This is accomplished at regular management meetings involving senior managers of the company together with the head of the central HSE department. Such meetings are intended to review the latest data on environmental performance, trends, deviations from predetermined objectives and targets, how effectively the environmental program has been implemented, etc.

When necessary, a review meeting may lead to decisions to modify or adapt the environmental objectives, the program, or even the policy if this seems justified.

With this last element the environmental management system "loop" is closed.

3. Environmental Communication

3.1. Environmental Communication: A New Aspect of Management

Traditionally, industry and particularly the chemical industry have not been models of good communication with society; indeed, secretiveness and confidentiality were deeply entrenched in the cultures of many reputable companies.

Starting with the disclosure of financial information, however, enterprises have increasingly adopted a more open attitude.

A similar evolution has occurred in the environmental domain: a few decades ago, no company would have considered going beyond minimal "instructions for use" on the labels of their products. Then came recognition of the "duty-to-inform," mostly in the form of information provided to the local community in the vicinity of an industrial site regarding actions to be taken in case of an accidental emergency at the plant. Finally, the public "right-to-know" was recognized by industry, first in North America, then in Europe, and ultimately even in Japan, where public-opinion pressures are less severe.

This is not to say that there is now full transparency on HSE matters between industry and society. It is worth noting in this context that environmental organizations talk in terms of "corporate disclosure," whereas industry prefers to talk in terms of "corporate communication and reporting." Some companies still believe that the public is interested only in being told about risks to which they are exposed, not absolute figures regarding emissions of dangerous substances. Industrial property rights are often used as an argument to limit disclosure.

Nevertheless, environmental communication is now featuring in the environmental policy of a growing number of companies, and it is developing rapidly across the world chemical industry.

A number of factors explain this trend:

1) The disclosure of environmental information has become compulsory under some existing national legislation (see Section 4.4). In the future more legal requirements are expected in many countries.
2) Within the broad concept of "sustainable development" (→ Sustainability and the Chemical Industry – Ethical Aspects and Approaches) environmental reporting has been identified as a major challenge for industry. As mentioned in the Agenda 21 document [5], "companies are encouraged to report annually on their environmental records, as well as on their use of energy and natural resources."
3) The credibility of industry, in particular of the chemical industry, is poor in the eyes of the public. Providing data on environmental performance (showing not only positive achievements but also difficulties and failures) can help restore industry's image and build credibility.
4) Customers have begun to integrate environmental considerations, including the environmental performance of suppliers, into their purchasing decisions.
5) Shareholders, financial institutions, and the insurance branch require information to help them assess the real present and future financial risks to which companies they are dealing with are exposed.
6) Employees and local communities need information about their working and living environments.
7) Environmental NGOs are likely to campaign more aggressively against corporations that give the impression they have something to hide about their environmental performance.

In fact, more and more companies consider environmental reporting to be a definite competitive advantage and a major factor in their "license to operate".

3.2. Audiences and Vehicles

Many different stakeholders in society have an interest in environmental information supplied by industry. The key ones include:

Local and national governmental agencies
Local communities
The general public
Media (general and specialized)
Employees
Shareholders
Banks, financial institutions, and insurers
Domestic and trade customers
Schools, colleges, universities, and business schools
Environmental NGOs

Satisfying the needs of these various audiences may require specific vehicles for environmental communication. Some examples of appropriate communication forms are:

Labels. The chemical industry has for several decades been using regulatory or standardized labels, in particular for hazardous products. Specification sheets, such as the standardized "Material Safety Data Sheets" (MSDS), provide

supplementary information on the hazards and risks of chemicals for various user categories.

Product advertising increasingly includes some environmental information. To limit the use of ill-founded or misleading statements, certain industrial organizations have drafted special guidelines on the matter [6]. The eco-labeling schemes operative in the EC and other countries represent a form of regulated environmental advertisement.

Media, including the general press and TV, are becoming increasingly interested in the environmental performance of enterprises. However, they are attracted more by bad news than good news, and the publicity afforded by the media to unfortunate accidents or incidents may seriously endanger a company's reputation.

Company newsletters and *magazines* offer a privileged form of support to environmental information directed at employees or shareholders.

"*Open house"* days and *plant visits* provide the best opportunity to convey environmental information about a site to local communities (including local media and environmental organizations), to employees, and to schools and other educational bodies.

"Hot lines", toll-free telephone numbers, and *information centers* are being made available by some companies to their customers and the public.

3.3. The Environmental Report

The concept of an environmental report, especially an annual environmental report, is becoming more and more popular among corporations in North America and Europe, and also Japan. Many companies consider the annual environmental report as a key element in their environmental communication strategy.

Because this concept is still in its infancy (the first full free-standing environmental reports were published in the late 1980s or early 1990s), there is as yet no standard or commonly accepted format for such reports. What follows is therefore simply a review of current trends, which may evolve significantly in the coming years.

3.3.1. Audiences

The annual environmental report is certainly the communication vehicle best suited to the needs of a number of audiences, in particular the employees, local communities, shareholders and financial institutions, environmental organizations, etc.

This underscores a major difficulty in the concept of the annual environmental report: finding the right style and the right balance between technical information, financial data, and easy-to-understand words, graphs, and figures. From the experience gained so far it is apparent that some reports would benefit from an improvement in style and presentation.

3.3.2. Corporate or Site Reports

Perhaps for fear of local adverse reactions, some corporations publish only a report covering the company as a whole, with consolidated data. However, if the report is to meet the needs of local communities and local audiences it is obvious that data pertaining to the site in question must also be published.

This fact is accepted by a growing number of companies. Some publish a single report with a section for the entire corporation together with various sections dealing with individual sites; others publish a corporate report supplemented by free-standing individual reports for their (main) sites.

3.3.3. Contents of the Report

Some reports are still mainly textual, providing only a few numeric figures for principal indicators, generally consolidated at the corporate level. Certainly reports should include a significant textual part, presenting, for example, the company's environmental policy, its environmental program and organization, the major achievements, objectives, and targets. However, a growing need is perceived to publish numerical data for both corporate and site reports as a response to the now recognized "right-to-know" of the public. Indeed, publishing such numerical data within a report offers a definite advantage

over provision of the "dry" figures required under certain legislation: the figures are put in the perspective of a real business (size of the site, products manufactured, etc.), thus avoiding – at least partially – easy misinterpretation by certain groups.

It is mentioned in Section 2.5.2 that some companies establish "environmental indices" from measured data on emission. Certainly such indices are useful for demonstrating the trends in environmental performance, but using them as a substitute for the publication of absolute figures can generate harsh criticism from some concerned stakeholders.

Another issue of concern is whether reports of all companies (at least in the same industrial sector) should include data covering the same parameters for a company or a site. This is certainly reasonable in terms of environmental relevance. Furthermore, one cannot deny the right on the part of many stakeholders (including regulatory authorities) to undertake certain comparisons between companies and sites, and this consideration would also militate in favor of a certain comparability of data. At least a "core list" of common parameters should be included in all reports.

In order to improve transparency and consistency of the reports the European Chemical Industry Council (CEFIC) issued in 1998 the Responsible Care – Health, Safety and Environmental guidelines. It lists 16 core parameters and their definitions according to which all chemical companies will report. The collation of comparable data will allow monitoring continual improvements.

3.3.4. Links to Environmental Management Systems

Environmental communication is not *stricto sensu* an element of the EMS. However, it is becoming more and more accepted that the results of environmental audits – at least those not containing confidential information, the disclosure of which could endanger competitiveness – must be made public. The EC Regulation on EcoAudits (see Section 4.3) requires the publication of a "public statement" after every audit. Site environmental reports would be a perfectly appropriate support vehicle for these statements.

3.3.5. Trends

There are many indications that corporate environmental reports, published at regular intervals, will eventually become obligatory for all major companies, in particular in the chemical industry.

The quality and quantity of information disclosed in the reports is likely to evolve. A research study [7] has identified five stages in the way environmental reports develop to meet the stakeholders' information needs:

1) Green "glossies," newsletters, videos; short statements in annual reports
2) One-off environmental reports, often linked to a first formal policy statement
3) Annual reporting, linked to an environmental management system but providing more text than figures
4) Provision of full environmental performance data on an annual basis, available on diskette or on-line, with an environmental report cited in the annual report
5) Sustainable-development reporting linking environmental, economic, and social aspects of corporate performance and supported by indicators of sustainability

Presently, most examples of environmental reports meet the definition of stage 3; only a few have reached stage 4. To attain stage 5 companies will need to develop and adopt methodologies for full environmental cost pricing and life-cycle assessment of their activities and products.

3.4. Stakeholder's Reactions

The argument most commonly used by those reluctant to embark upon environmental communication is a fear of adverse reactions from various groups within society. Experience shows, however, that with the necessary skills and precautions, the release of environmental information and in particular of annual environmental reports generates only occasional negative reactions, and that the benefits definitely outweigh the difficulties.

For example, local communities and employees always welcome environmental information, especially that related to specific sites. Shareholders and financial analysts have begun to

take an interest in environmental reports, but are likely to demand deeper assessments. The media have reacted positively to the release of environmental reports, but may be critical of reports that are too "textual." Environmental organizations are for the moment granting the benefit of doubt to corporations strongly involved in environmental reporting.

Certainly the credibility of information released by companies, in particular by those with a poor public image, may become an issue, and it will take some time for companies to demonstrate that the information they publish is candid and accurate. This has prompted some companies to request validation of their information, in particular of their environmental reports, by independent third parties, such as accredited inspection organizations. For the moment, few reports have received such external validation, but several companies envisage having future reports validated by reputable, undisputed third-party organizations.

3.5. Who Communicates?

Many companies still have a policy of relegating the responsibility for environmental communication to their professional communicators, backed as far as technical information is concerned by staff people in the HSE department. Professional communicators will always be needed to coordinate a company's information policy and define its rules and practices, but there is a recent trend toward inviting line and staff managers to participate in environmental communication. For example, open house days obviously involve many employees, who must be prepared to answer questions about a company's environmental performance. Site managers or superintendents may also be interviewed by journalists or media reporters, and employees are the company's best ambassadors in the local community.

Involving various levels of HSE managers in communication becomes all the more important when a communication crisis bursts following an accident in a plant, for example, or at any event attracting the attention of the media. All companies and sites should establish crisis management plans, duly tested and identifying all the major players, especially with respect to communications. There have been too many examples of accidents or isolated incidents that have ruined several years of effort by reputable companies to build trust with the public, simply because communications have been poorly managed during the event.

Many companies now include communication as an element in their training programs, in particular in the training of their HSE specialists.

4. The Impact of Legislation on Environmental Management

Complying with regulatory standards is clearly an important element of any environmental management system. The purpose of this section is not to describe all legislative texts applicable to industrial activities, but rather to identify major trends in environmental legislation influencing the management of chemical companies.

4.1. Operating Permits

Any industrial operation is subject to the granting of a permit by the competent authority. The dossier submitted with an application should include all information required to evaluate the environmental impact of the planned operation. It is then up to the authority to establish conditions that may be attached to the permit. These conditions might in some cases mandate a revision of certain processes or procedures as they were initially envisaged by the applicant. The permit process therefore implies a dialogue between the authority and the applicant, and it also implies the release of information to members of the public who might be affected by the planned operation. Even if the power of decision remains with the authority, the result of such consultation might be quite important for some "sensitive" operations, such as waste disposal sites. The whole permit process can extend over several years, which underscores the extent to which environmental questions can impact on industrial management decisions.

Certain conditions attached to such a permit are of a managerial nature (e.g., emergency plans, reporting lines, etc.). Most of them, however, establish emission limit values (ELVs) for

a list of relevant substances or indicators (waste, energy, noise, etc.) that the planned operation is expected to meet at all times.

In theory, these ELVs should result from a risk assessment process, starting with a definition of environmental quality objectives (EQOs) for the area concerned. Defining an EQO is a political decision by the authority: the fact that the area in question is of a residential nature, for example, or that rivers should continue to sustain aquatic life, and so forth. EQOs lead to the determination of environmental quality standards (EQSs) for every environmental compartment, such as the maximum concentration of SO_2 permitted in the atmosphere or heavy-metal limits in water, the maximum level of noise, etc., which in turn make it possible to achieve the EQOs. EQOs are fixed at the local level, or more often internationally, on the basis of scientific assessments. Finally, a model is used to calculate various ELVs of the planned operation to ensure that the EQOs are met, taking into account the existing levels of various parameters in the area concerned. This process, although complicated and possibly leading to discrepancies between the conditions of similar operations in different areas, is the only one that can assure that the environmental risk of an industrial activity is limited to an acceptable level while at the same time being optimally cost-effective.

Nevertheless, another process is becoming increasingly popular for establishing ELVs: the use of *"best available technique*" (BAT). A BAT may be defined as that set of technical and managerial processes and procedures available at a given time which provides for the most cost-effective manufacture of a certain product with minimal impact on the environment. The use of BAT is attractive to the authorities because it simplifies the process of establishing ELVs. It may also attract industrialists, because it ensures a "level playing field" for all companies in a particular business. However, it does raise certain questions, such as how long a BAT remains a BAT before becoming outdated by a new development, the possibility that some developers might enjoy a monopolistic situation, or the best way of ensuring that EQOs are met in heavily industrialized areas.

Whatever the process chosen for determining the ELVs, it is necessary that an integrated approach be adopted so that the impact on all compartments of the environment is minimized: taking care that atmospheric pollution, for example, is not transferred to the aquatic environment. A series of modern legislative texts follows this trend, including the EC Directive on Integrated Pollution Prevention and Control (IPPC).

4.2. Process Safety Legislation

Safety, because of its probabilistic aspects, cannot be regulated simply by standards. Assessing the accidental risk of an activity with respect to both equipment and management practices is therefore the key to safe operation (→ Plant and Process Safety).

In principle, regulation is impossible because, at least in the chemical industry, every case is a special one. However, legislation can require an operator to carry out a risk assessment and present the results to the authorities. Here again, a dialogue between the competent authority and the applicant will determine the level of acceptable risk and various conditions the activity should satisfy to meet this acceptable risk.

EC Directive 96/82/EC, the "Seveso" Directive, now being revised, is typical of legislation that fixes not a standard, but a management practice (i.e., the risk assessment procedure) in order to achieve its objective.

4.3. The EC Eco-Management and AuditRegulation

In 1993, the EC Council adopted a Regulation (EEC/1836/93) introducing a "Voluntary Community Scheme of Eco-Management and Audit (EMAS)." The initial intent was to facilitate development of environmental auditing practices within industry, but it was soon recognized that environmental audits could not be isolated from environmental management systems, and the title and content of the regulation were modified accordingly.

An enterprise deciding to take part in the scheme is committed to take the following actions:

1) Carry out an initial review of its environmental performance

2) Establish an EMS
3) Conduct periodic environmental audits of its various sites
4) Produce a "public statement" after each audit
5) Have the public statement "verified" by an independent and accredited third party

When the competent national authorities have satisfied themselves that a particular enterprise has complied with the requirements of the regulation they then grant what is known as a "statement," which the company is free to use at its discretion.

The regulation includes annexes specifying the elements of an EMS, the content and methodology of environmental audits, the role of verifiers, and the requirements for accreditation.

At the end of 1998, some 2 000 industrial sites won EMAS registration. Around two thirds of these registrations are in Germany, whereas the take-up elsewhere has been patchy. Many companies went to the ISO 14 001 certificate instead and were not willing to duplicate part of the efforts in order to get an EMAS registration, which is limited to Europe and does not offer tangible additional benefits.

The Regulation is currently revised and is likely to show the following features:

– EMAS will no longer be limited to "sites" but will be open to "organizations", which is in line with ISO 14 001
– The environmental management requirements of ISO 14 001 will be taken over as this will facilitate the step towards EMAS
– EMAS will retain a number of specific aspects which, in addition to the (extended) environmental statement, will differentiate it form ISO 14 001

Industry welcomes the alignment with ISO 14 001 but remains concerned that in the absence of any regulatory relief for EMAS registered companies many companies will stay with ISO 14 001

4.4. Mandatory Environmental Communication

Operating permits require an operator to monitor emissions and all other parameters subject to ELVs, and to report the measured results to the competent authority. In many countries, including the EC Member States, legislation of the "Freedom of Information" type make any information (especially environmental information) collected by governmental authorities available to the public, either upon request or directly at the initiative of the authorities themselves. In addition, many statutes related to accidental risk, such as the EC Directive on Major Hazards (the "Seveso" Directive) require active informing of any population likely to be affected by an accident from a chemical site [8]. Through this mechanism a form of mandatory environmental communication already exists in many countries.

Some countries have gone further in requiring industrial activities to measure the emissions of a specific list of substances and then report them to a "register" freely available to the public, sometimes on-line or on diskettes. In the United States, for example, the 1986 Emergency Planning and Community Right-to-Know Act (EPCRA) introduced under Section 313 of Title III the concept of the Toxics Release Inventory (TRI) [9]. Under this legislation, companies employing more than 10 full-time employees must provide the EPA with annual emission data for some 300 toxic chemicals manufactured, processed, or used in excess of certain threshold amounts. Data on emissions released and waste generated by individual sites are made available to the public through printed reports and electronic databases.

Certainly the introduction of the TRI has met the expectations of many stakeholders; it has also been a powerful incentive to industry in the United States to monitor and reduce its emissions and waste generation. It should be recognized, however, that making raw data available out of context opens the door to considerable misinterpretation, for example, identifying the largest companies or sites as "major polluters."

Certain other countries, in Europe and elsewhere, also maintain registers of the TRI type, albeit ones that are less comprehensive and less readily available. The EC has been considering introduction of a "Polluting Emission Register," possibly modeled along the lines of the TRI.

5. Voluntary Action by Industry

Environmental legislation, however comprehensive and detailed it may be in many industrialized countries, cannot cover all the cases encountered in day-to-day industrial practice. Moreover, legislation is rigid, and it cannot be adapted to follow the pace of technological and managerial development. It is also not the most cost-effective approach, because it requires that resources be committed to inspection and enforcement. Finally, the pressure of legislation is not perceived as a real motivation on the part of the workforce.

This has induced industry, led by a few large, advanced companies, to develop voluntary environmental activities and programs. These steps have been further encouraged by industrial associations and supported by certain enlightened governments. Some of the resulting acts can be seen as full substitutes for legislation. More often they complement existing legislation in facilitating its implementation and bridging gaps that legislation cannot cover.

Voluntary corporate action can take several forms. These are described briefly below, before focusing on the worldwide chemical industry initiative known as Responsible Care.

5.1. Internal Statements

Several elements of the environmental management systems discussed in Chapter 3 constitute voluntary actions, provided they are not made mandatory, for example, through an extension of the EC Eco-Management and Audit Regulation (see Section 4.3). These include in particular:

1) The HSE policy (see Section 2.3); this policy, endorsed at the highest level of corporate management, states the principles and objectives that govern management as far as HSE matters are concerned
2) The environmental program (see Section 2.5.2), which defines actions to be taken in a certain area to reach an objective within the framework of a set timetable

Both overall environmental policy and specific environmental programs are internal management tools, even if many companies publicize them (or at least a few of their environmental programs, avoiding the disclosure of competitively sensitive information) in their annual environmental reports. Experience shows that the drafting of a set of environmental programs contributes greatly to the development of environmental awareness within the workforce.

5.2. Voluntary Agreements

At the other extreme of the spectrum are "voluntary agreements" signed between a company and an authority for the purpose of achieving a target, with the choice of means left to the company.

The term "voluntary agreement" may not appear strictly appropriate: in one sense, entering into an agreement is always a voluntary action; on the other hand, the alternative to not signing such an agreement is, in most cases, a law. Other terms are sometimes used as well, in particular "covenant."

The components of a voluntary agreement are:

1) The *aim*; e.g., an emissions reduction target, a labeling scheme, the phaseout of a certain product, etc.
2) The *parties to the agreement*:
   a) On the governmental side, a local authority (e.g., for reduction of discharges to water from a site), a national government (for a global plan involving an industrial sector), or the EC Commission (although monitoring the implementation may be left to national authorities).
   b) For industry, the most straightforward case is when the agreement is signed by a company, but when the agreement covers an entire industrial sector at the national or regional level, the responsible party is usually the trade association concerned. This immediately raises the problem of the extent of the authority an association may be able to wield over its members.
3) The *penalties* in case of failure to achieve the aims of the agreement. Some agreements include financial penalties; this may lead to serious difficulties if the agreement has been signed by a trade association. More often the penalty is simply that a statute is subsequently enacted, which is more burdensome and less cost-effective for both parties.

4) A *monitoring system* and an *administration* to facilitate implementation of the agreement. Experience has shown that this can be done through light, cost-effective organizations.

The following examples are representative of voluntary agreements within the chemical sector:

1) The "33/50 Program" signed between the U. S. Environmental Protection Agency and a number of chemical companies for the voluntary reduction of their emissions of 17 of the most polluting substances by 33 % in 1992 and by 50 % in 1995 relative to 1988 levels
2) EC Commission Recommendation 90/437/EEC of June 1990 formalizing a voluntary program of reduction in the use of chlorofluorocarbons by the foam plastics industry, represented by its European associations
3) EC Commission Recommendation 89/542/EEC introducing a voluntary system of detergent labeling under the control of the European industry federation of detergent manufacturers
4) The various "covenants" signed between the Dutch government and Dutch industry associations for implementing the National Environment Policy Plan (NEPP) of 1989, which established a long-term policy and a program of reduction of emissions, negotiated within the various sectors

5.3. Public Commitments

Half-way between internal statements and binding agreements are the various forms of public commitments by which a company, through its President or CEO, commits itself to adopting an environmental behavior expressed in a set of principles.

There are indeed certain similarities between this form of voluntary action and the voluntary agreements discussed above:

1) The principles define the aims of the commitment. In general they are drafted in the form of a set of 10 – 15 short guidelines. For effective, practical implementation these must be supplemented by Codes of Practice or Guidance Notes.
2) The principles are drawn up by an organization such as the national or international trade association of the industrial sector concerned, and then endorsed publicly by the senior management of individual member companies.
3) The other party is the public, in general represented by environmental non-governmental organizations (NGOs) that check company environmental performances against the content of the corresponding guiding principles. Companies may suffer a severe penalty when failure to implement the principles is publicized by a credible NGO.

The best known example of such a commitment is the "Business Charter for Sustainable Development" launched by the International Chamber of Commerce (ICC) in April 1991, and now endorsed by over 1100 major corporations around the world [10]. The Charter is a set of 16 principles covering various aspects of the integration of environmental considerations into management practice, such as: environmental policy, continuous improvement of environmental performance, employee education, research, technology transfer, impact assessment, product and services stewardship, sound design and operation, contractors and suppliers, emergency preparedness, dialogue with stakeholders, and reporting.

The ICC Business Charter for Sustainable Development is recognized as a major driving force for continuous improvement in the environmental performance of enterprises through voluntary public commitment. Similar sets of guiding principles have been established by a number of national and international organizations. Some are less comprehensive than the ICC Business Charter, especially with respect to the requirements on research, product stewardship, and reporting; others stress specific aspects, such as emergency preparedness or overseas operations. Two of these Codes are perhaps worthy of special mention.

One is the set of CERES principles (formerly the "Valdez" principles), drawn up in 1989 by the Coalition for Environmentally Responsible Economies (CERES) after the Exxon Valdez oil spill [11]. Signatory companies, based mostly in

the United States, are particularly committed to environmental reporting (see Chap. 3) and compensation for environmental damage.

A second is the Global Environment Charter, launched in 1991 by Keidanren, the Japanese Federation of Economic Organizations [12]. The Keidanren Charter emphasizes the role of corporations in technology transfer, including transfer to developing countries, but does not require public reporting.

5.4. Responsible Care

Several chemical companies are signatories to the ICC Business Charter or other sets of principles like those mentioned above. But most also take part in "Responsible Care," the chemical industry's own initiative that originated in 1984 in Canada and is now spreading throughout the world [13].

5.4.1. Responsible Care; What Is It?

Responsible Care relies on two fundamental features:

1) A commitment by company leaders to seek continuous improvement in the environmental performance of a company's activities, including employee involvement and relations with customers and the society's stakeholders. This commitment is expressed by the signature of the company President or CEO on a set of Guiding Principles.
2) A program established and operated by national chemical industry associations to assist their member companies in implementation of the Guiding Principles and verification of the true achievements resulting from their commitments.

5.4.2. The Guiding Principles

There is not a single set of Responsible Care Guiding Principles: these are instead established on a national basis by the corresponding chemical industry associations with consideration directed to local circumstances. However, the Principles everywhere are remarkably similar in content and format; indeed, they are all modeled along the lines of other well-known principles, such as the ICC Business Charter for Sustainable Development or the CEFIC Guidelines for Protection of the Environment.

5.4.3. National Programs

Similarly, the details involved in facilitating and monitoring specific programs are left to national chemical industry associations, who must adapt them to local considerations such as the national legislative framework, the state of industrial development, the companies' cultures, etc. However, to ensure consistency in the initiative in the various countries, all national programs are expected to include seven fundamental features:

1) A formal *commitment* on behalf of each company to a set of guiding principles (see above. In the majority of cases the commitment is signed by the company CEO, but in some countries it is fulfilled by endorsement by the Board of the national association).
2) A series of *codes, guidance notes*, and *checklists* to assist companies in implementing the commitment. In some countries (e.g., the United States) a set of detailed codes has been drafted to cover the following areas: control of emissions, process safety, occupational health and safety, transport and distribution, community awareness and emergency response, and product stewardship. Elsewhere, especially in Europe, relevant associations had already developed a number of guidance documents on environmental management long before the introduction of Responsible Care. Producing and updating such codes and guidance documents is a continuing process.
3) The progressive development of *indicators* against which improvements in performance can be measured. In general, these indicators include sets of emission data for a number of selected substances and data on waste generation and recycling, as well as data on energy consumption and accidents.
4) An ongoing process of *communication* on HSE matters with interested parties outside the industry. The issue of environmental communication, discussed in Chapter 3,

is therefore an integral part of Responsible Care. Obviously the recommendations provided by the association to its member companies regarding the communications process influence the selection of indicators of performance.

5) Provision of *fora* in which companies can share views and exchange experiences on implementation of their commitments. Some associations provide extensive service to their member companies in the organization of seminars, workshops, local cells, etc. This is particularly valuable for increasing the motivation of people who in general do not respond easily to environmental concerns, such as sales managers or line middle-managers.
6) Adoption of a *title* and *logo* that clearly identify a national program as being consistent with and part of the concept of Responsible Care. The standard logo (Fig. 4) has been registered in many countries, and is used throughout the world by the chemical industry. Many associations, even in non-English speaking countries, have retained the registered term "Responsible Care;" others have adopted a different expression that communicates in translation the spirit of the term Responsible Care.

Figure 4. The Responsible Care logo

7) Consideration of the best ways to encourage all member companies to *commit to* and *participate in* Responsible Care. Many associations have made or will make company commitments to Responsible Care a condition of membership. This implies that if a company does not fulfill its commitment, the association has the right to expel it. Before taking this extreme action, however, strong peer pressure will be exerted by other members on the noncomplying company.

5.4.4. The Scope of Responsible Care; Product Stewardship

Responsible Care is sometimes understood as covering nothing more than the manufacturing activities of a company. Fundamentally, however, the Guiding Principles of Responsible Care apply to all aspects of industrial operation, from basic research to product development, manufacture, distribution, and use. They are thus more nearly consistent with a "cradle-to-grave" approach.

In this respect, product stewardship is a vital component of Responsible Care. Product stewardship may be defined as "the responsible and ethical management of the health, safety, and environmental aspects of a product throughout its life cycle, from its design to manufacture and distribution, including resource consumption, transport, and final disposal options."

Responsible Care therefore aims at developing an "environmental culture" among all employees of a company, whatever their position and function. Researchers are motivated to assess the HSE effects of a new product at an early stage of development, and to find substitutes if the risk appears unacceptable. Engineers develop processes with a concern for minimal consumption of resources and the lowest possible impact on the environment. Production people operate their plants safely, and with full respect for environmental standards. People in charge of transport and distribution seek the safest means of transport. Sales managers advise their customers on the safe use of products, including problems raised after normal use to avoid creating waste problems.

5.4.5. The Challenges of Responsible Care

The successful development of the Responsible Care initiative by chemical industry in many

countries throughout the world entails two major challenges:

1) Finding ways to maintain the integrity of the initiative as national associations adapt their programs to local conditions and cultures – which may vary significantly among countries like the United States, Japan, and the nations of South America, Europe, or Africa. In addition, Responsible Care is a chemical industry initiative, but other industrial sectors more or less closely related to the chemical industry would benefit from similar programs adapted to their specific needs.
   The International Council of Chemical Associations (ICCA) has established a procedure for checking the consistency of programs developed by national associations against the seven fundamental features, both at the time of introduction of the program and periodically thereafter. The ICCA has also established rules for "partnership" with other industrial sectors that deal with chemicals (transport and distribution companies, waste disposal contractors, etc.) and are also interested in Responsible Care.
2) Finding ways to make Responsible Care acceptable and credible to the public, regulatory authorities, and environmental organizations. Responsible Care is not simply a publicrelations exercise: it is based strictly on improved performance – not on words, but on actions. Credibility therefore will be gained by demonstrable achievements, which will need to be communicated effectively. Many national programs include "public advisory panels" consisting of representatives of the various stakeholders; others have developed alternative channels of communication, but all companies are encouraged to adopt an open attitude toward information.

Honest dialogue between industry and the public and between plants and local communities is a crucial element in bringing about the industry-wide cultural change required by Responsible Care, and in building public confidence and trust, a key to enabling the chemical industry to retain its "license to operate."

6. Standardization and Certification of Environmental Management Systems

As discussed in Chapter 2, companies first establish policies for health, safety, and environmental matters, and then set up environmental management systems to ensure that objectives defined in the policies are effectively achieved.

An EMS cannot really be defined by law, even if the EC Eco-Management and Audit Regulation (see Section 4.3) does describe the basic elements of an EMS and encourages companies to establish such EMSs. Conversely, leaving the companies without adequate guidance on how to establish an EMS may result in serious discrepancies in the structure and organization of EMSs as adopted by individual firms, with the accompanying risk of some stakeholders coming to question the credibility of the EMSs of certain companies.

This dilemma has led to the concept of standardization of environmental management systems. In addition to helping companies achieve their objectives, appropriate standards can, through certification, offer assurance to others that the stated objectives will be achieved.

6.1. Standards for Environmental Management Systems

6.1.1. Generic or Specific Standards

Although there is a long history associated with the drafting of standards for product specifications, testing methods, etc., the concept of standards for management systems is quite new: it indeed first appeared in the mid 1980s with the issuance of the series of standards for quality management systems ISO 9000 (and its national or regional equivalents, EN 29 000, BS 5750).

Whereas the ISO 9000 standards were restricted in their initial scope to that which was necessary to achieve product quality, it was soon recognized that the same requirements could also have a generic interpretation, and that, for example, the ISO 9001 and ISO 9004 standards could be adapted to cover environmental management systems.

Nevertheless, a few standardization bodies undertook the drafting of standards specific to

EMS, such as BS 7750 (see below), issued in 1992. A few similar national standards have since been issued elsewhere, and the International Organization for Standardization (ISO) is taking the same route.

A certain number of standardization bodies share with some industrialists the view that there should be further development of the concept of a generic management-system standard. The standard would include appendices covering specific requirements for product quality, environmental management, etc. The vision is that this structure would eventually replace the emerging sets of separate management-systems standards, but it probably will not come to pass for several years.

6.1.2. EMS Standards

In March 1992 the British Standards Institute (BSI) issued the first standard specifically designed for environmental management systems, under the reference BS 7750. In April 1993 the Association Française de Normalisation (AFNOR) published an experimental standard (X30-200) which, although somewhat different in its wording, follows the same structure as the British Standard.

Under the impulse of S. Schmidheiny from the Business Council for Sustainable Development, the International Organization for Standardization (ISO) established in 1991 a Strategic Advisory Group on the Environment (SAGE). The ISO-SAGE in turn created six subgroups, one of them in charge of making recommendations on a standard for EMS. In June 1993 the work of ISO-SAGE was taken over by a new Technical Committee (TC): ISO/TC 207, "Environmental Management."

Six subcommittees (SC) were set up

- SC 1 – Environmental management systems (ISO 14 00x series of standards)
- SC 2 – Environmental auditing (ISO 14 01x series of standards)
- SC 3 – Environmental labeling (ISO 14 02x series of standards)
- SC 4 – Environmental performance evaluation (ISO 14 03x series of standards)
- SC 5 – Life cycle assessment (ISO 14 04x series of standards)
- SC 6 – Terms and definitions ISO 14 05x series of standards)

The first standards were issued in 1996. Amongst them ISO 14 001 (Environmental management systems – Specification with guidance for use) which has since substituted all national EMS standards.

6.1.3. The ISO 9000 and 14 000 Standards

There has been a growing perception that although separate standards may be required for quality and environmental aspects for management systems, these standards should be made as compatible as possible. Compatibility is understood to mean that the common elements (e.g., training, auditing, document control, etc.) of the standards can be implemented without unnecessary duplication or the imposition of conflicting requirements.

In 1998, ISO therefore decided that ISO 14 001/14 004 should be revised in advance of its envisaged revision schedule, in an effort to make it as compatible as possible with ISO9001/9004 which are currently subject to fundamental revision. Both series of standards would then be simultaneously issued in 2000.

6.2. Certification of Environmental Management Standards

Standards for management systems, in addition to their "educational" aspects, also allow for "certification" (or "registration") of the activity covered by the standard by an independent, accredited third party, thus giving confidence to the company and outside stakeholders that the objectives of the management system will be achieved.

6.2.1. Certification of an EMS

Certification is a process in which a certification body (often a commercial firm) assesses a particular system against the relevant standard and then issues a certificate of compliance. This is followed up with a series of regular surveillance visits (usually once or twice a year). Certification bodies may themselves be accredited for this

function by a governmental or similar agency, lending additional credibility to their work and resulting in an "accredited certification."

ISO has developed standards for the auditing of an EMS and has furthermore decided to develop a common auditing standard for quality and environmental management systems (see Section 2.6.3). The latter will lead to significant savings for the industry as one single accredited certification body will be able to certify both management systems.

It can be expected that the existence of a certificate awarded by an international or national accredited body will become increasingly important to regulators and stakeholders as a form of assurance regarding the professionalism of the company and its EMS. This will assist many companies in meeting the key objective of being able to demonstrate and promote their management of environmental issues in a tangible and credible way. Lack of certification will in time increasingly expose a company to multiple audits by customers seeking to satisfy themselves with regard to the company's environmental probity.

6.2.2. Certification Against the EC Regulation

One article in the EC Eco-Management and Audit Regulation stipulates that "Companies implementing national, European or international standards for environmental management systems and certified, according to appropriate certification procedures, as complying with those standards, shall be considered as meeting the corresponding requirements of this Regulation . . ." (certification, however, will not exempt the "environmental statement" from being validated by a certified verifier).

The introduction of this article was of crucial importance as a way of linking the Regulation and voluntary participation on the part of companies to certification against the standards for EMS; because the public statement is an integral part of the scheme, it will quite normally be "verified" by the certification body as a standard part of the certification process.

The revised EMAS Regulation will now formally take on board the environmental management system requirements of ISO 14 001 (see Section 4.3).

7. International Aspects of Environmental Management

Most chemical companies, at least above a certain size, operate in several countries. In some cases all the countries may be at a similar state of development, but both industrialized and developing countries may also be involved. Especially in the latter case, special consideration must be given to environmental management to avoid the problems that too often have tarnished the images of "multinational" or "transnational" companies.

7.1. Environmental Requirements in Different Countries

Many reasons, mostly of a commercial nature, may prompt a company to establish an operation in another country, one of which might be a less stringent environmental legislative atmosphere in the host country. There have been a few cases in which "relocation" of a company's activity from its home country to another was perfectly justified because of the sudden introduction of exceptionally stringent environmental legislation not considered sensible or appropriate by most countries, even the most developed ones. Unfortunately, however, there have been more cases in which companies have established operations in countries with little environmental legislation simply to benefit from standards less demanding and costly than those reasonable standards in effect in their home country. Such "double-standard" practices, including in the environmental domain, have contributed significantly to the bad reputation associated with "multinationals" by some environmental organizations and the governments of some developing countries.

These practices are no longer considered to be ethical by reputable corporations that, in their foreign operations, comply not only with local legislation but also with their own company standards, which are generally equivalent to or exceed the requirements of their home country.

This is a basic principle expressed by many companies in their environmental policies.

It must be recognized, however, that companies of foreign parentage following this course of action put themselves in a position of competitive disadvantage vis-à-vis local companies satisfied with complying, at lower cost, only with national environmental requirements. Foreign companies can sometimes overcome this difficulty by "educating" both national companies (e.g., through the intermediacy of national chemical industry associations) and local governments in modern aspects of environmental protection. The role of transnational corporations in raising the environmental awareness and behavior of developing countries is now clearly recognized [1, Chap. 3.III].

7.2. Technological Cooperation

Technological cooperation between countries at different levels of development has been identified as a key component of sustainable development.

Technological cooperation between companies in industrialized and developing countries can take several forms:

Technical Assistance. A company or an organization sends experts to a company requesting expertise and assistance, perhaps for an audit of environmental performance, a troubleshooting mission, an education or training session, etc. The mission might be accomplished on a commercial basis, but more often it is carried out under the aegis of a voluntary program operated by an industrial association, a government, or an international organization.

Transfer of Technology. A company makes available, within the terms of a commercial contract, a process or a technique to which it holds title, generally as the result of a research and development program on its own premises. Such a transfer of technology should obviously include technological cooperation before, during, and after actual start-up of the operation.

Foreign Investment. A company may elect to set up its own operation in a foreign country, either in the form of a fully owned subsidiary or as a partnership with some other company at an appropriate level of equity. The industrial operation might be built from a green site, or the foreign investor might acquire an existing facility. In general, any such foreign investment implies a transfer of technology from the home company to the foreign one.

Several industrial associations have produced guidelines for an environmentally sound transfer of technology [15].

1. Introduction

Noise abatement is an essential consideration with respect to chemical and petrochemical plants for the protection of people living in the vicinity of such a plant as well as employees working at the facility. Reduction of workplace noise within a plant also increases the intelligibility of public announcements or warning signals, at the same time that it facilitates communication among personnel on the plant floor and in the control rooms. Moreover, extraordinary noise events are more conspicuous in a quiet environment, so measures that limit background noise contribute to improved safety conditions. Effort to counter excess vibration of plant equipment in general has the further advantage that it can prevent unnecessary damage and consequent disruption of productive activities.

2. Definitions

2.1. Sound and Vibration Levels

Audible sound refers to mechanical vibration with components falling in the approximate frequency range 16 Hz – 16 kHz. Sound in gases and liquids is always related to vibrational motion of the particles constituting the fluid. Important *field quantities* with respect to sound are the time variation in the associated alternating pressure $p(t)$ (which is superimposed over some static pressure) and the time variation of the velocity $v(t)$ with which the affected particles move back and forth.

The root mean square (rms) value p of the alternating pressure $p(t)$ is commonly expressed in terms of a logarithmic function, the *sound pressure level* L, which is measured in decibels (dB). L is defined by the relationship

$$L = 20\log(p/p_0)\ \mathrm{dB} \tag{1}$$

The reference value p_0 (for airborne sound) has been internationally fixed at $p_0 = 2\times10^{-5}\ \mathrm{N/m^2}$, a value that corresponds to the human auditory threshold at medium frequencies. A compelling reason for selecting a logarithmic scale is the fact that the alternating pressures of interest from a technical standpoint cover a range of eight orders of magnitude.

Other field quantities used to describe sound energy or sound-energy transfer can be derived through multiplication. Thus, the *intensity* I

$$I(t) = \overline{p(t)\cdot v(t)} \tag{2}$$

specifies the power (i.e., energy per unit time) that will penetrate a standard surface perpendicular to the velocity vector. The overbar in Equation 2 indicates a time-average value. The *sound power* $W(t)$ can be derived by forming the surface integral:

$$W(t) = \oint_S \overline{p(t)\cdot v(t)}\cdot\cos\varphi\,\mathrm{d}S \tag{3}$$

where φ is the angle between the velocity vector $v(t)$ and a line normal to the surface element $\mathrm{d}S$.

The rms value W of the sound power $W(t)$ is also expressed in terms of a logarithmic measure (again with the unit decibels) known as the *sound-power level* L_W:

$$L_W = 10\log(W/W_0)\ \mathrm{dB} \tag{4}$$

For airborne sound sources, the value $W_0 = 10^{-12}$ W is normally used as a reference point.

Mechanical vibrations in solids can be characterized by three motion quantities and their variations as a function of time. These are the time variations of the displacement $s(t)$, velocity $v(t)$, and acceleration $a(t)$. The three quantities can be interconverted by integration or differentiation:

$$a(t) = \frac{\mathrm{d}v(t)}{\mathrm{d}t} \quad \text{and} \quad v(t) = \frac{\mathrm{d}s(t)}{\mathrm{d}t} \tag{5}$$

All three measurable variables cover large ranges, so – just as in the case of sound pressure – rms values are often reported rather than the quantities themselves, in logarithmic form (once again in decibels) as the corresponding levels L. These levels are defined by the relationships

$$\begin{aligned} L_s &= 20\log(s/s_0)\ \mathrm{dB} \\ L_v &= 20\log(v/v_0)\ \mathrm{dB} \\ L_a &= 20\log(a/a_0)\ \mathrm{dB} \end{aligned} \tag{6}$$

The following have been established as reference values for computing velocity and acceleration levels (according to international standards; see ISO 1683 [1]):

$$\begin{aligned} v_0 &= 10^{-9}\ \mathrm{m/s} \\ a_0 &= 10^{-6}\ \mathrm{m/s^2} \end{aligned} \tag{7}$$

However, in the field of acoustics it is usually recommended that a somewhat different set of reference values be utilized instead:

$$\begin{aligned} s_0 &= 8\times10^{-12}\ \mathrm{m} \\ v_0 &= 5\times10^{-8}\ \mathrm{m/s} \\ a_0 &= \pi\times10^{-4}\ \mathrm{m/s^2} \end{aligned} \tag{8}$$

Using these reference values, the three structure-borne sound levels L_s, L_v, and L_a all share a common numerical value at a frequency of 1000 Hz, and the average sound-pressure level directly in front of a vibrating structure corresponds to the average structure-borne sound level.

2.2. Level Calculations

Studies in the field of sound and vibration usually involve individual sound signals that are not coherent relative to one another (i.e., they do not depend on each other). The power quantities in such a case are found to be additive according to the following addition rule:

$$L_{\text{total}} = 10\log\left(\sum_{i=1}^{n} 10^{0.1\cdot L_i}\right)\ \text{dB} \tag{9}$$

where

L_{total} = total level
L_i = ith individual level
n = number of individual levels to be added

This relationship can of course also be reversed. If, for example, level L_1 is to be subtracted from level L_2, the following calculation leads to the level L_{Diff} representing the differential value:

$$L_{\text{Diff}} = 10\log\left(10^{0.1\cdot L_2} - 10^{0.1\cdot L_1}\right)\ \text{dB} \tag{10}$$

Just as in addition, any averaging of incoherent signals must also be carried out using power quantities. The following expression can be used for obtaining an energetic mean value:

$$L_{\text{m}} = 10\log\left(\frac{1}{n}\sum_{i=1}^{n} 10^{0.1\cdot L_i}\right)\ \text{dB} \tag{11}$$

where

L_{m} = energetic mean level (level of the average value),
L_i = ith individual level,
n = number of individual levels to be averaged

The above arithmetic rules apply to all the various level quantities, including the sound-power level, acceleration level, etc.

The average level of a time-dependent (variable) sound-pressure level $L(t)$, expressed over an average time T, is called the (energy) *equivalent continuous level* L_{eq}, defined according to the following expression:

$$L_{\text{eq}} = 10\log\left(\frac{1}{T}\int 10^{0.1\cdot L(t)}\,\text{d}t\right)\ \text{dB} \tag{12}$$

The significance of L_{eq} is that it permits a time-dependent noise function to be replaced by an equivalent constant noise with the same energy.

If a time-dependent variable noise consists of n time periods with individual durations T_i and corresponding sound-pressure levels L_i, where the latter are constant over the course of the stated durations, then the following expression is valid:

$$L_{\text{eq}} = 10\log\left(\frac{1}{T}\sum_{i=1}^{n} T_i\, 10^{0.1\cdot L_i}\right)\ \text{dB} \tag{13}$$

where

$$T = \sum_{i=1}^{n} T_i$$

The equivalent continuous level L_{eq} is the function most often used to assess the effect of time-dependent sound on human beings.

2.3. Spectra

In addition to considering its variation as a function of time (i.e., sound pressure vs. time), a particular vibration event can also be described in terms of its spectrum, in which case the vibrational quantity is expressed as a function of frequency f. Measuring instruments with filters – so-called fast Fourier transform (FFT) analyzers – are generally used for this purpose, since they make it possible to establish levels within discrete frequency ranges. Most important for practical applications is filtering in octave bands, where the transmission band selected has a range of one octave. The relationship between the lower and upper frequency limits for such a transmission band is 1 : 2. The octave-band central frequencies are uniformly determined; sound-pressure levels L_{oct} in octave bands are generally provided for the following central frequencies f_n:

$$f_n = 31.25 \times 2^{n-1} \text{ with } n = 1 - 9 \tag{14}$$

In addition, it is also common to use third-octave bands or narrow-band spectra with constant bandwidths.

3. The Impact of Noise and Vibration

3.1. Sound Perception and Noise Effects on Humans

Audible sound covers a frequency range of 3 decades and a sound-pressure range of ca. 7 decades; in a double-logarithmic presentation of sound pressure versus frequency (Fig. 1), the *audible range* is represented by the area between the threshold in a quiet situation ("threshold in quiet," the lowest audible sound level for a pure tone) and the threshold of pain.

Figure 1. Hearing area; i.e., the area between the threshold in quiet and the threshold of pain; the area encompassed by music and speech and the limit of damage risk are also indicated.
The ordinate scale is expressed not only in terms of sound-pressure level but also with respect to sound intensity and sound pressure. The dotted part of the threshold in quiet relates to subjects who frequently listen to very loud music (based on ZWICKER and FASTL [2]).

Figure 2. Equal-loudness contours for pure tones in a free sound field.
The parameter is expressed in terms of loudness level, L_N. The 3-phon curve also represents the threshold in quiet. A-Weighting curves have been provided for comparison (dotted) at two levels (based on ZWICKER and FASTL [2]).

Vibrations at very low frequencies ($f < 16$ Hz, infrasound) and very high frequencies ($f > 20$ kHz, ultrasound) cannot be perceived by the human ear. In Figure 1 the region encompassed by speech and music is hatched, and a limit of hearing-damage risk has been indicated for a noise exposure of eight hours per day.

At a constant sound level, sound with a low or very high frequency will not elicit the same loudness sensation as that in the medium-frequency range. This is illustrated by curves of equal loudness (Fig. 2). Figure 2 shows that a 100-Hz tone at L=50 dB, for example, is perceived as being of the same loudness as a 1000-Hz tone at $L = 40$ dB.

In order to simulate this hearing characteristic in the measurement of sound levels, a *weighting filter network* (*A-filter*) with defined attenuation at low and high frequencies is used to approximate a loudness-equivalent measuring result. This A-weighting curve stems from the early days of sound measurement; examples of weighting curves are provided in Figure 2.

Figure 3. Typical sound-pressure levels for everyday noise sources

The A-weighting curve is constant at all levels, while the loudness sensation (i.e., the shape of the equal-loudness contours) varies with level. From Figure 2 it is apparent that an A-weighted sound-pressure level approximates the loudness sensation better in the medium-level range than at high sound levels. In spite of this, A-weighted sound-pressure levels, indicated by dB (A), are generally used for the measurement and assessment of sound events. The

A-weighting curve is internationally standardized (IEC 651 [3]). Additional weighting curves are defined for special applications (e.g., B-, C-, D-weighting). Currently accessible, more accurate measurement methods for ascertaining hearing-adjusted loudness have not yet gained general acceptance (e.g., ISO 532 [4]). Figure 3 illustrates a number of typical everyday sound-pressure levels.

Noise can impair or destroy human hearing, and it can also cause physical or mental stress (increased pulse rate and/or blood pressure, nervousness, sleep disorders). Furthermore, noise can increase the risk of an accident if warning signals go undetected because of excessive background noise. These effects are particularly important to consider in the assessment of workplace noise.

There is no evidence to indicate that noise with a sound-pressure level below 85 dB (A) can directly impair the ear. In terms of continuously present noise and its average A-weighted sound-pressure level $L_{\mathrm{A,m}}$, biological effects are now commonly accepted as follows:

disturbance of a night's rest	$L_{\mathrm{A,m}} > 40\,\mathrm{dB\,(A)}$
disturbance of concentration	$L_{\mathrm{A,m}} > 45\,\mathrm{dB\,(A)}$
disturbance of communication	$L_{\mathrm{A,m}} > 50\,\mathrm{dB\,(A)}$
increased risk of cardiovascular disease	$L_{\mathrm{A,m}} > 65\,\mathrm{dB\,(A)}$

These noise effects are relevant factors in any assessment of noise in residential neighborhoods located near industrial zones or roads.

The hearing-impairment effect of noise depends heavily on the sound-pressure level of the noise itself as well as on the corresponding exposure time. Irreparable damage can be caused even by single transient sound events (shots, explosions) with peak values exceeding ca. 140 dB (A). Long-duration noise exceeding 85 dB (A) (e.g., at the workplace) leads to short-term impairment of hearing capacity (*Temporary Threshold Shift,* TTS), from which the ear will recover during periods of silence. Based on empirical data, ISO 1999 [5] provides a mathematical model for calculating damage-probability distributions for populations exposed to noise. The calculation model uses the following input quantities:

1) The A-weighted equivalent continuous noise level over an 8-h period (noise-rating level) expressed in dB (A)
2) Exposure time in years
3) Age in years
4) Sex

A rule of thumb for calculating a maximum permissible continuous noise level at the workplace, one that will not lead to permanent hearing impairment even after years of exposure, is expressed by the following formula:

$$L_{\mathrm{A,m}} \leq 85 + 10\log\left(24/T_{\mathrm{n}}\right)\,\mathrm{dB\,(A)} \tag{15}$$

where

T_n = daily noise-eposure time in hours

According to this model, no irreparable hearing damage is to be expected at levels up to 90 dB (A) with a working time of eight hours per day.

If the ear is exposed to noise levels higher than those recommended, sensory cells (hair cells) located in the inner ear will be destroyed, leading to permanent hearing impairment (*Permanent Threshold Shift,* PTS).

Wearing ear protectors at continuous noise levels > 85 dB (A) can prevent or reduce temporary shifts of the hearing threshold, and the danger of permanent damage is also considerably reduced.

3.2. Effects of Vibration on Humans and Equipment

Vibration becomes distinctly noticeable above a certain magnitude. The threshold for vibration perception depends on the frequency. In the range 5 – 100 Hz, the perception of vibration is nearly proportional to velocity. Vibrations in this frequency range will be felt if their velocity exceeds 0.1 mm/s. Vibrations with velocities of ca. 0.4 – 1.6 mm/s are clearly recognizable, and those up to ca. 6.3 mm/s are strongly felt. Vibrations with frequencies < 5 Hz must be more intense before they will be perceived.

Increasing vibration impact results in an observable impairment of well-being and fitness; higher values endanger the health and may even lead – depending upon the exposure time – to

permanent injury. The effect produced by vibration depends on the point at which the vibrations penetrate the human body. Sitting or standing individuals may suffer alteration of the skeleton (spine) and internal organs. Vibrations passing through the hands and arms can cause peripheral circulatory problems, nervous disease, and alterations of the bones, joints, and muscles of the hand – arm system (white-finger syndrome).

The vibration of plant equipment may also lead to physical damage or work disruption if it exceeds a certain magnitude (e.g., vibrational cracks at ducts, mechanical breakdown, structural damage, etc.).

4. Legal Aspects

In all highly industrialized countries, noise is recognized as a dominating incident factor in the human environment. Impairments caused by the effects of other vibration are of minor importance, but they do occur. Measures designed to reduce noise and vibration in industry and trade are likely to prevail only if appropriate laws are enacted, because achieving the desired end entails extra costs, and it may sometimes complicate plant operation and maintenance. Regulations aimed at protecting individuals from noise and vibration are directed toward immission levels in the vicinity of industrial plants as well as immission at the workplace. It is only natural that such rules have developed differently in various countries, excluding the possibility of our providing a detailed examination in the context of this article of the many specific regulations.

4.1. Occupational Noise

Regulations directed toward noise within the plant (e.g., noise at the workplace) are essential to protect workers from hearing impairment. As indicated in Section 3.1, most countries have established 85 dB (A) as the limit for permissible noise at the workplace, and this value should not be exceeded if it can be avoided by technical means. Ear protection should be worn at any workplace with a noise-rating level ≥ 85 dB (A). Moreover, workers exposed to such high noise levels should have their hearing regularly checked by a specialist in industrial medicine.

4.2. Occupational Vibration

Rules related to the human effects of vibration at the workplace are necessary in order to protect the staff from injury and restrictions with respect to their performance and fitness, particularly at workplaces associated with plant safety (e.g., control rooms, etc.). ISO 2631 [6] defines limits for vibration effects based on the criteria "reduced comfort boundary," "fatigue-decreased proficiency boundary," and "exposure limits" for whole-body exposure as a function of frequency and daily exposure time (see Fig. 4). ISO 5349 [7] deals with criteria for assessing vibrational effects on the hand – arm system.

4.3. Environmental Noise and Vibration

Regulations with respect to noise in the general vicinity of industrial plants are concerned not with potential hearing damage but rather with protection from disturbance and noise pollution. Although the annoyance caused by industrial noise and vibration from industrial plants is relatively minor compared to road and rail-traffic noise, industrial noise sources tend to be overrepresented from the standpoint of complaints.

ISO 1996 [8], consisting of three parts, provides a set of international regulations for noise protection in residential neighborhoods located near industrial areas. The basic quantity used for describing sound immission is the A-weighted energy-equivalent continuous-level L_{Aeq}. The noise-rating level L_{Ar} that has been proposed assumes the probable need for additional charges K_1 related to tonality and K_2 for impulsive noise components as follows:

$$L_{\mathrm{Ar}} = L_{\mathrm{Aeq}} + K_1 + K_2 \,\mathrm{dB\ (A)} \tag{16}$$

ISO 1996 lists additional measurement quantities that permit a detailed description of sound immission even for fluctuating or single-sound events. National or local authorities must establish appropriate noise-limiting values that should not be exceeded by the noise-rating levels in affected neighborhoods. The magnitude of the limiting value, the extent of additional charges

Figure 4. Transverse (A) and longitudinal (B) acceleration limits as a function of frequency and exposure time. "Fatigue-decreased proficiency boundaries" (based on ISO 2631-1 [6]); to obtain "exposure limits," multiply the acceleration values by 2 (6 dB higher); for "reduced-comfort boundaries" divide acceleration values by 3.15 (10 dB lower)

for tonality and impulsive noise, and the evaluation procedure itself vary not only from country to country but sometimes even within different states or regions of the same country. In general, nighttime noise limits are 10 – 15 dB lower than those for the daytime; some countries also define intermediate values for the early morning and evening hours.

Noise-limiting values also depend on the type of structures present in the immission area. In some countries, the lowest limit is 35 dB (A) at night for residential areas. The highest allowed value is typically 70 dB (A) for both day and night for industrial zones in which appartments are permitted only in exceptional cases. It can generally be expected that residential use without major disturbance will be possible if a value

of 45 dB (A) is not exceeded at night. Compliance with respect to the limits is usually checked by taking measurements 0.5 m in front of an open bedroom or living room window.

Like the limiting values for sound immission, limits for vibrational immission also differ from country to country. The vibrational immissions of chemical plants operating up to current technical standards are considerably below the threshold for vibration perception, so problems with vibrational immission are quite unlikely in the vicinity of such plants.

5. Vibration

5.1. Measurement

Generally speaking, all three of the motion quantities described in Section 2.1 can be used for the measurement of vibration.

The displacement of a vibrating structure has an easily measurable magnitude only at very low frequencies. For this reason measurements of displacement itself are rarely performed. It is much easier to measure the related motion quantities (velocity and acceleration) and then convert these into the quantity of interest.

Geophones are used for detecting vibrational velocity. These are moving-coil sensors with characteristic frequencies tuned to the lower end of the transmission range. Such characteristic frequencies often fall within the relevant measuring range, so appropriate correction networks are required. Because of the way geophones are constructed, their industrial range of application is rather narrow.

Accelerometers are piezoelectric transducers with characteristic frequencies tuned to the upper end of their transmission range. These are universally applicable for measuring vibrations, and many designs and models are available for use in a wide variety of situations. Accelerometers are almost always utilized for modern industrial vibration measurements.

Measurement techniques are prescribed in such individual regulations as ISO 2631 [6] (effects on man) and ISO 2372 [9] (machine vibrations). Modern digital instruments are used for registering and evaluating the signals, a process that may include frequency analysis, use of weighting filters, etc. Continuously registering instrumentation is recommended for monitoring vibrations from critical equipment in which standstill might lead to expensive downtime or safety-relevant incidents.

5.2. Principal Sources

Vibration is produced by all types of machinery involving rotating or reciprocating masses, including pumps, compressors, turbines, motors, centrifuges, and mills.

ISO 2372 [9] provides severity criteria for assessing machine vibration as a function of the nature and size of the device. Equipment with strong vibrational emissions must be isolated from areas subject to protection by specially installed foundations or resilient mountings. This is especially true for machines associated with extensive vibration, such as rocking conveyors, oscillating grates, etc. Figure 5 illustrates severity criteria for various types of machine vibration.

Figure 5. Vibration-severity criteria for the range 10 – 1000 Hz (based on ISO 2372 [9])

Pipelines may be subject to high vibration levels due to pulsating flow (e.g., piping associated with piston or screw compressors). Such

vibration may even be amplified by system resonance caused by an unfavorable arrangement of pipe supports. Tear-offs and, in the case of continuous stress, fatigue fracture of the pipes themselves can be the result. Furthermore, vibrating pipes may cause vibrations in other parts of a plant. Figure 6 illustrates criteria applicable to the evaluation of piping vibration.

Figure 6. Criteria for piping vibration levels

6. Sound Emission

The sound emission from a sound source can be described fundamentally in terms of a corresponding sound-pressure level L. Since this measure depends upon distance from the sound source, some indication must also be provided of the measuring distance. However, it is always preferable to work with a single numerical value for the description of a sound emission, namely the sound-power level L_W (see Section 2.1), which is generally supplemented with a spectrum (e.g., in octave bands).

6.1. Determination of Sound-Power Levels

There are various methods available for laboratory or field measurements intended to establish sound-power levels. The most important procedures applicable to industrial plants are described below.

Measurement in Hemianechoic Space. The hemianechoic space method can be applied to sound sources or sound-source groups characterized by free sound propagation. The corresponding temporally and locally averaged sound-pressure level L_{m} is measured on a surface with a total area S that encompasses the sound source and terminates at a set of reflecting boundary surfaces (e.g., the floor). The measuring surface is in most cases a cuboid with surfaces located (preferably) 1 m from the contour of the sound source. Based on the assumption that sound waves pass perpendicularly through the measuring surface, the sound-power level L_W is then:

$$L_W = L_{\mathrm{m}} + 10 \log\,(S/S_0)\ \mathrm{dB} \tag{17}$$

where $S_0 = 1\ \mathrm{m}^2$

For more details (exact position of the measuring points and correction for surroundings, noise level, etc.), ISO 3744 [10] should be consulted.

Method Applicable to Multi-Source Industrial Plants. This method, described in ISO/DIS 8297 [11], can be applied to large industrial plants with numerous sound sources provided the major extension of the plant (up to ca. 300 m) is horizontal. Sound-pressure levels are determined on a single measuring path that encloses the entire plant. The required height of the microphone depends on the size of the plant and the distance between the plant contour and the measuring path; a typical value is 5 – 15 m. A unidirectional microphone can be used to reduce the influence of background noise (for more details see ISO/DIS 8297 [11]). This measuring approach is easy to apply (measuring time ca. 4 h for a plant occupying 40 000 m^2), and it establishes both a sound-power level and an octave-band spectrum for all noise radiated by the plant.

Vibration Measurement. The airborne noise power radiated by a vibrating surface can be determined by measuring the corresponding vibration. This technique is most often applied when a direct measurement of airborne sound is impractical because of excessive background

noise. A vibration-measuring instrument is used to establish a temporally and locally determined velocity level L_{vm} at the surface of the radiating structure (surface S). The radiation behavior of a structure can be described either by the radiation efficiency σ or the logarithmic measure $10 \log \sigma$. The radiation efficiency depends on the ratio of the radiated airborne wavelength to the size of the radiator, the geometric form of the radiator, and the phase distribution of structure-borne sound over the radiator surface. The sound-power level L_W is obtained from the quantities L_{vm}, S, and σ as follows:

$$L_W = L_{\mathrm{vm}} + 10 \log\,(S/S_0) + 10 \log \sigma \,\mathrm{dB} \tag{18}$$

where $S_0 = 1\ \mathrm{m}^2$

For more details see ISO/TR 7849 [12]. This procedure is generally not as accurate as the direct measurement of airborne sound because of an often insufficient knowledge of the radiation efficiency. A value of $\sigma = 1$ provides an upper limit for the sound-power level.

Measurement of Sound Intensity. In contrast to indirect methods for the determination of sound intensity and sound power by sound-pressure measurements, sound intensity [see Eq. (2)] can also be measured directly with the aid of a two-microphone method and digital two-channel FFT analyzers for data processing. Details regarding the measurement of sound power by the intensity method are available in ISO 9614 [13]. Part 1 of this standard describes the method for obtaining data at discrete points on the measuring surface. Part 2 (in preparation) describes a scanning method that is often easier to apply. With the scanning method, a measuring probe is led continuously along a set of adjacent measuring paths that cover the entire measuring surface. Intensity measurements are seldom applicable to industrial plants.

6.2. Flow-Induced Noise

In refineries and chemical or petrochemical plants much of the noise generated is due to the flow of gases or liquids. For this reason it is appropriate at this point to provide a brief introduction to sound generation by flow mechanisms.

Part of the flow energy in any flow field is converted into sound energy. At subsonic flow speeds, flow noise is generated by sources of three types: monopole, dipole, and quadrupole.

A *monopole* source exists if an unsteady volume flow is responsible for the noise generation. Typical examples result from periodic afflux of fluid into a pipe or collapsing cavitation bubbles. Periodic afflux into a pipe is responsible for the low-frequency noise emitted by piston and screw compressors. If the local pressure in a flowing liquid falls below a certain critical value (approximately equal to the vapor pressure of the liquid), then the presence of appropriate nuclei can cause gas- and vapor-filled bubbles or cavities to develop and grow. This phenomenon, which is typical of all liquids, is called (hydrodynamic) *cavitation*. Such bubbles can collapse violently if the external pressure increases above the critical pressure, giving rise to very high local pressure peaks (sometimes exceeding 10^5 bar with strong cavitation, sufficient to cause material damage) and also to high noise levels. Cavitation usually generates a rattling, broadband type of noise. Noise generation by cavitation is important with respect to valves and pumps.

In the case of a *dipole* source the volume flow is locally constant, but alternating forces are present as well, such as at the surface of a solid object encountering a stream generated by vortex shedding or interacting with a turbulent incoming flow or a turbulent efflux. This type of noise generation is particularly important in the case of fans and valves.

If the alternating forces also tend to compensate each other, then the corresponding noise sources are of the *quadrupole* type, as observed with free turbulence. Such quadrupole sources are sometimes important in conjunction with valves or vents to the open air.

Theoretical considerations have shown that with respect to the sound power W of the three different types of elementary sources, velocity dependencies can be anticipated as listed below provided the frequencies typical for the noise behavior and the characteristic velocity U (e.g., the flow velocity) are proportional to each other and the sources are also "compact."

Source	*Sound power*
Volume flow (monopole)	$W \sim \varrho c^3 M^{2\ldots4}$
Alternating force (dipole)	$W \sim \varrho c^3 M^{4\ldots6}$
Free turbulence (quadrupole)	$W \sim \varrho c^3 M^{6\ldots8}$

where

ϱ = density of the flow medium
c = sound velocity in the flow medium
U = characteristic velocity
M = U/c (the Mach number)

This table shows that in a sound field composed of different types of sources that are active simultaneously, the sources of higher order become more conspicuous with increasing Mach number compared with those of lower order. This is the reason why quadrupole sources are of no significance in liquids, where the Mach number is small.

Figure 7. A-weighted sound-power levels of important noise sources in chemical and petrochemical plants based on state-of-the-art noise abatement; solid line = process furnaces, steam boilers; broken line = induced-draft cooling towers; hatched area = fans, compressors, pumps, steam turbines, gears, valves, coal mills

6.3. Major Sources of Noise

The main individual sources of noise in chemical and petrochemical plants are:

- Burners (process furnaces, steam boilers, and flares)
- Fans
- Compressors
- Pumps
- Electric motors
- Steam turbines
- Gears
- Valves
- Exhausts to the open air
- Granule conveyors and silos
- Airborne splash noise from cooling towers
- Coal mills
- Belt conveyors

Reference values for the A-weighted sound-power levels of noise generated and radiated to the outside by these sound sources as a function of installed power are illustrated in Figure 7 based on state-of-the-art noise-control measures.

6.3.1. Burners (→Combustion)

The noise-radiation level of a process furnace, steam boiler, or flare is determined by the nature of the burner. Burner noise is generated by turbulent combustion of gas and oil, turbulent efflux of gaseous fuel through the burner nozzles, and the efflux of steam added to improve combustion. Important quantities associated with combustion noise include heat release and the extent of turbulence in the flame.

In the case of *furnaces* and *boilers*, the burner nozzles are located inside a room. The resulting noise is of a broadband nature with peaks attributable to characteristic frequencies of the combustion room and the gas or air supply of the burner. Noise radiation takes place via air intakes from the surroundings (natural-draft burners), air flow into the air ducts and then into the open air (forced-draft burners), the furnace walls, and flue-gas ducts into the stack and then into the open air. Stack walls themselves are generally of minor importance.

The following noise-control measures are used to reduce burner-noise radiation:

1) Installation of silencers in the air inlets of natural-draft burners
2) Acoustically optimized furnace-wall construction
3) Acoustical treatment of the air ducts in forced-draft burners

Newly designed furnaces and boilers outfitted with currently available noise-control facilities are capable of meeting A-weighted burner-noise sound-power levels of

$$L_{WA} = 83 + 10 \log N \, \mathrm{dB\ (A)} \tag{19}$$

where N = heat release in MW (0.1 . . . 10 MW)

Flares are used for burning off small masses of gas resulting from leakage and changes in operating conditions, burn-off during controlled start-up and shut-down procedures, and burn-off occasioned by emergency shut-down of a process plant. Only elevated flares can be used for the emergency elimination of large masses of gas. Elevated flares are designed for gas-mass flows up to ca. 500 t/h. Ground flares are often used for smaller mass flows because combustion is more satisfactory with a ground flare than with an elevated flare. This applies not only to environmental stress occasioned by unwanted light radiation but also with respect to the emission of residual hydrocarbons in the flue gas. Furthermore, a ground flare is less noisy with the same gas-mass flow relative to the corresponding elevated flare [by about 10 – 20 dB (A)]. Ground flares are designed for gas masses up to ca. 70 t/h.

With a ground flare, noise is radiated via the air-intake openings and the flare mouth. It is customary to install silencers at the air-inlet side, which can reduce the A-weighted sound-power level to

$$L_{WA} = 102 + 15 \log q \, \mathrm{dB\ (A)} \tag{20}$$

where q = gas-mass flow in t/h (3 . . . 70 t/h)

6.3.2. Fans

Process plants most often utilize centrifugal and axial fans. The noise from a fan consists of a broadband component accompanied by specific tones. Noise sources of the dipole type are responsible for the broadband noise; these are caused by vortex shedding from the moving blades and turbulent flow acting upon solid construction parts. The specific tonal components are produced mainly by forces resulting from interactions between the moving blades and guide vanes in the case of axial fans and between blades and cut-off with centrifugal fans, both of which lead to periodically fluctuating streams flowing toward solid components.

The noise is radiated primarily via free openings on the suction or pressure sides of the fan, by ducts connected to the fan, and by the fan casing.

The following secondary noise-control measures are useful for reducing this radiated noise:

1) Installation of silencers at the suction and pressure sides of the fan, particularly for fans with free openings on either the suction or the pressure side
2) Acoustical enclosures, or wrapping of the fan casing
3) Acoustical wrapping of connected ducts

Such noise-control measures permit the achievement of an A-weighted sound-power level of

$$L_{WA} = 75 + 10 \log N_a \, \mathrm{dB\ (A)} \tag{21}$$

where N_a = rated electric power in kW (1 . . . 3000 kW)

Air coolers and induced-draft cooling towers are equipped with single-stage axial fans. In the case of low-noise fans (broad blades, large diameter, tip speed < 35 m/s), the corresponding fan noise can be brought down to an A-weighted sound-power level of

$$L_{WA} = 78 + 10 \log N_a \, \mathrm{dB\ (A)} \tag{22}$$

where N_a = rated electric power in kW (0.1 . . . 500 kW)

6.3.3. Compressors (→ High-Pressure Technology, Chap. 3.4.; → Refrigeration Technology, Chap. 1.1.2.)

Noise radiation from a compressor depends on the type of construction, the power, and the rate of revolution. The most common compressor types in chemical and petrochemical plants are piston compressors, turbocompressors (axial and centrifugal compressors), and Roots and screw compressors.

Piston Compressors. A piston compressor conveys a fixed mass of gas with each piston stroke. This periodic conveyance is in turn related to periodic pressure variations on the suction and pressure sides of the compressor. The noise spectrum that results is responsible for the noise level in the low-frequency range. High-frequency noise is produced by relief within the pressure valves, where flow rates often reach sonic speeds.

Sound radiation of the noise takes place via the compressor casing and the connected suction and pressure pipes, including pulsation dampers.

Turbocompressors. In axial-flow compressors, compression of the gas is achieved by rotating blade rings and rows of stationary or adjustable guide vanes. The corresponding noise spectrum consists of specific tones superimposed over broadband noise. The broadband noise is mainly caused by (a) alternating forces on the rotating blades due to vortex shedding at the back edge and by turbulent flow down stream from struts and intake nozzles, as well as (b) alternating forces on guide blades in the turbulent flow down stream from the rotor blades. Individual tones in the spectrum result mainly from periodic alternating forces due to interaction of the rotor blades with the guide vanes.

The noise generated by such a compressor is radiated via the connected suction and pressure piping (major portion), the compressor casing, and interstage coolers and separators.

Roots and Screw Compressors. Compressor noise in this case is due mainly to the periodic conveyance of gas and the flow and exhaust noise accompanying pressure-compensation phenomena at the pressure outlet.

Noise generated by such a compressor is radiated via the connected piping (major portion), the compressor casing, and the inlet (for air compressors). A sound-power spectrum for noise introduced into the connected piping can be determined quite accurately provided a time-dependent volume flow can be derived from the compressor's construction data.

Important secondary noise-control measures applicable to compressors include installation of pulsation absorbers and silencers in the suction and pressure pipes as well as acoustical wrapping of the connected pipes. These noise-control measures can result in the following A-weighted sound-power levels in the case of piston and turbocompressor noise:

Piston compressor

$$L_{WA} = 86 + 5 \log N \, \mathrm{dB\ (A)} \tag{23}$$

where N = required power in kw (50 . . . 1000 kW)

Axial turbocompressor

$$L_{WA} = 105 + 5 \log N \, \mathrm{dB\ (A)} \tag{24}$$

where N = required power in MW (0.3 . . . 20 MW)

If stringent acoustical requirements are in force, installation of a compressor within a building requires provisions for a suitable acoustical enclosure.

With Roots and screw compressors, auxiliary sound-absorbing enclosures are common, leading to an A-weighted sound-power level of

$$L_{WA} = 72 + 10 \log N \, \mathrm{dB\ (A)} \tag{25}$$

where N = required power in kW (10 . . . 300 kW)

6.3.4. Pumps (→ High-Pressure Technology, Chap. 3.3.)

Pumps can be divided into two main categories: hydrostatic and hydrodynamic. *Hydrostatic* pumps are used for the generation of very high pressures. One characteristic of these pumps is a mechanical separation between the suction and pressure sides. Furthermore, depending on the extent of this separation, the discharge pressure is almost independent of the counterpressure or lift of the pump. The most important types of hydrostatic pumps are the vane cell pump, the gear pump, the axial piston pump, and the spindle pump.

In contrast to hydrostatic pumps, *hydrodynamic* pumps (rotary pumps) provide no mechanical separation between the inlet and discharge ports. The pressure difference between the two ports must be maintained by hydrodynamic forces. Rotor blades introduce kinetic energy into the axially flowing liquid, energy that is transformed mainly into pressure energy. Fluid conveyance is continuous.

The major cause of noise radiation from pumps is alternating pressure within the pumped liquid. With respect to hydrostatic pumps, three different mechanisms can be responsible for noise generation:

1) Periodic alternation of the discharge
2) Impulse-like pressure-compensation processes at the point of intersection of liquid volumes that differ in pressure
3) Cavitation and gas exhaust during the suction process

Hydrodynamic pumps are associated with noise-generation mechanisms similar to those of fans. Furthermore, cavitation may arise under certain operating conditions in conjunction with the suction process at the rotating blades.

The major noise radiation from a pump occurs via connected pipes and the pump casing. An important secondary noise-control measure is acoustical wrapping of the pipes, leading to an A-weighted sound-power level of

$$L_{WA} = 70 + 10 \log N \, \mathrm{dB\ (A)} \tag{26}$$

where N = required power in kW (1 . . . 2000 kW)

If the acoustical requirements are rather strict, pumps must be installed within sound-absorbing enclosures or in separate buildings.

6.3.5. Electric Motors

Three-phase line-voltage electric motors are commonly employed for rated powers up to ca. 400 kW. Three-phase high-voltage electric motors (6000 V) are used for rated powers > 160 kW. The noise generated by electric motors is due mainly to associated blowers (in the case of air-cooled motors), magnetostriction, and the motor bearings. The extent of noise radiation from a modern electric motor depends on the motor's power and rate of revolution as well as the extent of built-in noise-control measures. In the case of 3000-rpm motors, level differences > 10 dB (A) may distinguish "normal" from "low-noise" types. Enclosures are necessary for large motors when the acoustical requirements are stringent.

For air-cooled line-voltage motors the following A-weighted sound-power level can be achieved assuming the use of low-noise blowers:

$$L_{WA} = 75 + 7 \log N \, \mathrm{dB\ (A)} \tag{27}$$

where N = nominal power in kW (3 . . . 400 kW)

For high-voltage motors with integrated noise control or a suitable enclosure, an appropriate target for the A-weighted sound-power level is

$$L_{WA} = 70 + 7 \log N \, \mathrm{dB\ (A)} \tag{28}$$

where N = nominal power in kW (160 . . . 3000 kW).

6.3.6. Steam Turbines

The noise generated by a steam turbine is due mainly to flow noise from within the turbine itself. This noise is probably caused by the same mechanisms operative in turbocompressors. Condensing turbines generate additional noise in the condensers.

Noise generated by a steam turbine is radiated via the casing and the steam-feed pipe as well as the steam-exhaust pipe and any condensers that may be present. The following secondary noise-control measures are effective for reducing noise radiation:

1) A sound-absorbing enclosure for the turbine casing
2) Combined heat and noise wrapping of the steam-feed pipe
3) Wrapping of the steam-exhaust pipe (and condensers) or installation of a silencer in the steam-exhaust pipe adjacent to the steam turbine

These measures can lead to an A-weighted turbine sound-power level of

$$L_{WA} = 95 + 7 \log N \, \mathrm{dB\ (A)} \tag{29}$$

where N = rated power in MW (0.3 . . . 20 MW)

6.3.7. Gears

Many investigations of gear noise and its origin have been described in the literature. The evidence suggests that there is a close relationship between dynamic load on the gear teeth (and therefore the service life) and resulting noise. In some cases it is possible to derive information regarding gear quality and gear defects from the nature of the radiated gear noise.

Geometric deviations and elastic deformation of the teeth are major sources of gear-noise generation. Uneven spots on the surface of the teeth arise during manufacture, and these cannot be avoided. As the teeth engage, the uneven spots are "played" like a phonograph record. Although the shape deviations are very small (ca. 10 µm), they can cause significant noise, which is generally of a broadband nature.

Flank deformations of the teeth are often due to defects in the driving gear of the tooth-cutting machine, and therefore display spatial periodicity related to tooth frequency and the rate of revolution of the gear-cutting machine. Flank defects generally cause frequency maxima that are related not to the meshing frequency of the gear in question but rather to the gear-cutting machine used for its manufacture.

A special case of tooth defect is *pitch defect*, caused by unequal spacing between the teeth. The noise produced by pitch defect displays peak levels at the harmonics of the rate of revolution. Under loaded condition, the teeth of a gear wheel are deformed slightly as a result of their elastic properties. This is an important factor with respect to noise generation, because such deformation changes as a function of time.

The most important factors associated with the generation of gear noise are geometrical deviations, alterations in tooth stiffness, specific tooth power, circumferential speed, alignment of the shafts, shaft bearings, and stiffness of the casing. These parameters interact in a complicated way that depends to some extent on design data (tooth geometry, wheel diameter, tooth width, etc.).

In order to reduce sound radiation, gears are often provided with acoustical wrappings and mounted resiliently. These measures permit the following A-weighted sound-power level to be met:

$$L_{WA} = 74 + 7 \log N \, \mathrm{dB\ (A)} \tag{30}$$

where N = rated power in kW (1 . . . 20 000 kW)

6.3.8. Valves (→ High-Pressure Technology, Chap. 4.)

Gas flow through control valves generates noise mainly as a result of the flow field down-stream from the narrowest cross section, especially via vortex shedding and turbulent-flow impact on solid construction elements (with alternating intensity, thereby constituting a dipole source), free radiation in the mixing zone (a quadrupole source), and compression shock when sonic speeds are reached or exceeded within the valve.

Noise control is generally unnecessary with valves for liquids so long as there is no cavitation or evaporation (flashing).

Noise generated by control valves is radiated mainly via the connected piping, not the valve casing itself. Noise-reduction features have been successfully incorporated into gas control valves in recent years, but process plants still typically require extensive additional secondary valve-noise control measures. These include sound-absorptive wrapping of the pipes (and sometimes the valve casing) and/or the installation of silencers between a valve and the connected pipes. These noise- control measures can lead to an A-weighted sound-power level for control-valve noise of

$$L_{WA} = 70 + 10 \log N_a \, \mathrm{dB\ (A)} \tag{31}$$

where N_a = power dissipated in the valve in kW (0.1 . . . 3000 kW)

6.3.9. Exhaust Noise

Chemical and petrochemical plants contain numerous valves for venting gaseous materials to the atmosphere. The corresponding noise is often characterized by very high sound power. Many of these are emergency valves engaged only in the case of an unforeseen incident, but during start-up or shut-down of a plant it often becomes necessary to blow out superfluous steam or air via so-called start-up control valves. Pressure relief and noise generation with respect to such installations is confined mainly to the valve and the vent opening.

The major sound-transmission paths are blow-out openings, pipes, and valve casings. Important noise-control measures include installation of valves with low-noise design characteristics, acoustical wrapping of valve casings and connected piping, installation of silencers (which generally consist of separate pressure-relief and absorption units) at the blow-out openings, as well as addition of sound-absorbing cladding to the silencer casing. These measures make it possible to achieve an A-weighted sound-power level of

$$L_{WA} = 95 + 10 \log q \, \mathrm{dB\ (A)} \tag{32}$$

where q = mass flow in t/h

6.3.10. Granule-Conveyor Piping (→ Solids Handling, Chap. 6.)

Pneumatic conveyance is widely used for transporting plastic granules between polymerization plants and silo facilities. The extent of sound radiation from a pneumatic conveyor line depends on the piping parameters (diameter, wall thickness, material), transport parameters (product throughput, transport speed), and parameters associated with the material conveyed (density, granule size, hardness).

Noise is produced by impact between the conveyed material and the pipe walls. Maximum excitation of the pipe occurs at bends because of the large impulse interchange that accompanies a turn.

The frequency spectrum of noise produced by granule conveyance is broadband in nature, consisting mainly of high-frequency components. Common noise-control measures include use of special steels instead of aluminum for the pipes (especially at bends), together with acoustical wrapping of both pipes and bends. If these measures are taken, the sound-power level of a granule-conveyor pipe can be reduced to less than

$$L_{WA} = 75 + 10 \log l \, \mathrm{dB\ (A)} \tag{33}$$

where l = pipe length in m

6.3.11. Water-Splash Noise from Cooling Towers

Apart from air coolers, most cooling towers in process plants are of a modular, rectangular design for the purpose of water recooling. The towers generally operate according to the principle of countercurrent or crosscurrent air flow, and are equipped with axial fans (see Section 6.3.2). Cooling of descending water takes place by evaporation and convective heat transfer (→ Cooling Tower Technology).

Fan drive is accomplished with an electric motor connected via a gear box. The fan hub itself is flanged directly to the output shaft of the gear box. In addition to noise produced by the fans, gears, and drive motors, much of the emitted noise is caused by water splash in the basin. Radiation of these water noises occurs via air intakes and the diffuser opening. A reasonable estimate of the A-weighted sound-power level of water noise is provided by the expression

$$L_{WA} = 69 + 10 \log q \, \mathrm{dB\ (A)} \tag{34}$$

where q = water throughput in m^3/h

In general, secondary noise-control measures are not necessary with the cooling towers found in chemical or petrochemical plants.

6.3.12. Coal Mills (→ Size Reduction)

Coal mills are an important source of sound in coal processing plants (power stations and coal gasification or liquification facilities). The following types of mill are used for crushing and pulverizing coal, depending on the quality of the crude coal and the technical requirements: ball triturators; bowl mills, cylinder crushers, and roller mills; and impact rotor mills or air-jet impact pulverizers.

The milling itself occurs according to the following principles:

In a ball triturator, steel balls are lifted by friction in a rotary drum at the interior steel cladding, causing coal to be ground by the impact of backfalling balls [A-weighted sound-power level: 114 . . . 129 dB (A)].

In bowl, cylinder, and roller mills the coal is crushed between rolling bodies and an appropriate grinding bowl [A-weighted sound-power level: 105 . . . 118 dB (A)].

In principle, an impact rotor mill resembles a centrifugal fan with blades designed to act as baffle plates. Crushing of the coal occurs as a result of impact with the rotating baffle plates and the armored casing [A-weighted sound-power level: 105 . . . 111 dB (A)].

Noise radiated by coal mills is derived from the following sound sources:

1) Impact noise produced as grinding balls strike the interior armoring of the milling drums (ball triturators)
2) Impact noise from coal striking a rotating impact rotor and the armored casing (impact rotor mills and air-jet impact pulverizers)
3) Crushing and rolling noise (bowl mills, cylinder mills, and roller mills)
4) Impact noise produced at the crude coal inlet
5) Driving motors and gears

6) Fan noise (impact rotor mills)

In order to reduce noise transmission, coal mills are installed in their own separate buildings. Provided careful attention has been paid to acoustical planning in the building concept, it is possible to achieve a coal-mill A-weighted sound-power level of

$$L_{WA} = 85 + 5\log N \,\mathrm{dB\,(A)} \tag{35}$$

where N = driving power in kW (10 . . . 2000 kW)

6.3.13. Belt Conveyors (→ Solids Handling, Chap. 4.)

Belt conveyors are usually used for transporting coal and slag in coal-processing plants. Such a conveyor consists of an endless belt that passes over two drums, the driving pulley and the tail pulley. Between the two pulleys the belt is supported by support rollers. One or more driving stations may be located at the head of the conveyor.

In defining the sound radiation due to a belt conveyor it is necessary to differentiate between noise from the driving station and noise due to motion of the band. The noise produced by the driving station is a function of the corresponding gears and driving motors. Sound radiation from motion of the band is due mainly to rolling noise generated by belt contact with the support rollers, together with bearing noise from the support rollers themselves. The belt speed is an important parameter with respect to overall noise level.

With a belt conveyor system an A-weighted sound-power level of

$$L_{WA} = 84 + 5\log q \,\mathrm{dB\,(A)} \tag{36}$$

where q = output in t/h
can be achieved if the following measures are taken:

1) Limiting the band speed to a maximum of 3 m/s
2) Use of low-noise bearings for the support rollers
3) Regular maintenance of the support rollers (i.e., replacement of defective bearings and support rollers)
4) Provision of an acoustical enclosure for the driving station

6.4. Sound-Power Levels Associated with an Entire Plant

Large-scale industrial plants typically exhibit the following noise characteristics:

1) Many individual sound sources spread over a large surface area
2) Relatively constant noise emission as a result of 24-h operation
3) Constant broadband background noise that provides little specific information since it results from the interaction of many discrete sound sources

For large-scale industrial plants, especially refineries and petrochemical complexes, the area-specific A-weighted sound-power level (also called the specific sound-power level) is an important parameter for estimating community noise levels, one that is being increasingly accepted, particularly with respect to land-utilization and building codes.

In order to avoid misunderstanding it is essential that uniform definitions be adopted. We therefore suggest the following definitions of specific sound-power levels $L_{W''A}$:

For a single plant within a larger complex:

$$L_{W''A} = L_{WA} - 10\log\left(\frac{S_a}{S_0}\right) \tag{37}$$

where

L_{WA} = A-weighted sound-power level of the plant in question
S_a = "Plant area"; i.e., the area occupied by an individual process plant or an auxiliary plant, including access areas within the plant but not the surrounding areas (access areas include open areas, roads, and main pipelines within the plant)
S_0 = 1 m^2

For an overall industrial complex:

$$L_{W''A} = 10\log\left(\sum_{\nu=1}^{n} 10^{0.1\cdot L_{WA\nu}}\right) - 10\log\left(\frac{S_C}{S_0}\right) \tag{38}$$

where

n = number of individual plants within the factory

$L_{\mathrm{A}v}$ = fraction of A-weighted sound-power level attributable to the vth individual plant within the complex

S_{C} = "Complex area"; i.e., the total area occupied by the complex, including storage tanks, administrative buildings, traffic areas, and car parks. Large open areas (fallow land) within the limits of the complex are not included.

On average, the following area ratios are typical:

$$\sum S_{\mathrm{a}}/S_{\mathrm{C}} \approx 0.05 \text{ for refineries} \approx 0.15 \text{ for petrochemical complexes} \quad (39)$$

For individual plants, production facilities, and auxiliary plants subject to currently available noise-abatement measures, specific sound-power levels fall within the following limits:

$$68 \leq L_{W''\mathrm{A}} \leq 82\,\mathrm{dB\ (A)} \quad (40)$$

The dispersion reflected in the specific A-weighted sound-power levels $L_{W''\mathrm{A}}$ for individual plants is relatively large. Therefore, acoustic predictions applicable to individual plants in relation to their area-specific sound-power levels are possible only for plants with similar operational conditions (including throughput, installed power, etc.).

Figure 8. Typical A-weighted sound-power spectrum in octave bands for refineries as well as chemical and petrochemical complexes
$L_{W\mathrm{A}}$ = A-weighted overall sound-power level; $L_{W\mathrm{A/oct}}$ = A-weighted sound-power level in octave bands

In the course of developing zoning and land-utilization plans, and for the determination of minimum distances applicable to refineries and chemical or petrochemical complexes, an A-weighted sound-power level ($L_{W''\mathrm{A}}$) of 62 dB (A) represents a reasonable estimate for assignment to the overall premises.

Figure 8 provides a standardized, typical octave sound-power spectrum of 0 dB (A) for refineries and chemical or petrochemical complexes.

7. Sound Immission

The sound immission associated with an industrial plant in its surroundings depends not only on sound emission within the plant and the distance from the point of immission but also on various topographical factors and, especially at distances of more than 200 m, factors related to the weather. Direct measurement of the noise-immission level due to an individual plant is often impossible as a result of inevitable background noise; in this case, immission calculations must be based on emission data collected within the plant itself.

7.1. Measurement of Sound Levels in the Vicinity of an Industrial Complex

The sound-pressure levels generated by a distant sound source vary considerably; e.g., by more than 20 dB (A) at a distance of 1000 m. This is due largely to changeable weather conditions, which are in turn associated with highly variable sound propagation. The highest sound-power levels are generally recorded when the wind is blowing directly from the plant to the receiver (i.e., under downwind conditions). The dispersion of measured values under downwind conditions is relatively small, so an *average* sound-pressure level under downwind conditions is the appropriate quantity for describing noise immission due to a plant. A downwind situation is defined as one in which the wind direction deviates no more than 60° from the line joining the sound source and the point of measurement.

Noise immission in the vicinity of a continuously operating industrial plant is generally measured at night because of the correspondingly lower traffic background noise levels. In general, all measurements should be conducted under downwind conditions, and an energetic mean value should be used based on at least three measurements. Addition of appropriate charges for

tonality and impulsive noise components leads to a corresponding noise-rating level (see Section 4.3). Such an assessment of noise immission should normally be based on the weather situation that actually prevails in the vicinity of the plant. If a downwind situation is to be expected at least 25 % of the year, then this weather situation, which supports sound propagation, is the one that must be taken as prevailing. If a downwind situation is relatively rare, a reduction of up to 5 dB (A) is permissible in establishing the long-term noise-rating level as a function of wind direction and speed, the frequency of temperature inversions, and the distance between the plant and the immission point. It is important to verify, however, whether relevant governmental regulations include provisions for such long-term assessments.

7.2. Outdoor Sound Propagation

Sound immission to be anticipated at a greater distance from the sound source can be determined through a sound-propagation calculation based on sound emission at the source. This calculation method is useful for an acoustic prognosis with respect to a plant still in the planning stage, as well as for an existing facility if background noise at the immission point prevents direct measurements.

ISO/DIS 9613-2 [14] suggests an international calculation approach that could be described as a semiempirical method. The complex physical phenomenon of sound propagation is divided into a set of individual steps described in empirical ways, based partly on physical considerations. Real sound sources are represented by point sound sources characterized by sound-power levels L_W. The sound-pressure level L at the immission point of interest under downwind conditions is then calculated according to the following equation:

$$L = L_W - A \tag{41}$$

where A is the sum of a series of attenuation terms, the most important of which are described below.

1) $A_{\mathbf{div}}$ *: Attenuation due to geometrical divergence.*

Sound from a point sound source propagates within a hemispherical space. This leads to a geometrically based level reduction:

$$A_{\mathrm{div}} = 10\log\left[4\pi\times\left(\frac{d}{d_0}\right)^2\right] = 20\log\left(\frac{d}{d_0}\right) + 11\,\mathrm{dB} \tag{42}$$

where d = the distance (sound source – immission point) in m, and $d_0 = 1$ m.
This means that a level reduction of 6 dB can be anticipated with a doubling of the distance.

2) $A_{\mathbf{atm}}$*: Attenuation due to atmospheric absorption.*
During airborne sound propagation, part of the sound energy is transformed into heat. This airborne absorption depends on the ambient temperature and the relative humidity of the air as well as on the wavelength (or frequency) of the sound. It is represented by the absorption coefficient α. The following expression characterizes the attenuation due to atmospheric absorption:

$$A_{\mathrm{atm}} = \alpha\times d\,\mathrm{dB} \tag{43}$$

The absorption coefficient increases with increasing frequency (e.g., at 500 Hz, $\alpha \approx 0.21$ dB/100 m).

3) $A_{\mathbf{ground}}$*: Attenuation due to ground effects.*
At larger distances, sound-level reductions are observed as a result of interference between the direct ray and sound rays reflected by the ground. Sound scattering and absorption in the surface layer of air is another important factor. The two effects are difficult to differentiate, and are expressed by the damping attenuation A_{ground}, which in turn depends on the height of the sound source, the height of the receiver, and the distance by which the two are separated. A_{ground} increases from 0 dB to 5 dB with increasing distance.

4) $A_{\mathbf{screen}}$*: Attenuation due to screening.* A "sound shadow" is always observed behind a physical barrier (e.g., a building, a row of houses, a wall, or a dam). Thus, the corresponding sound-pressure level is reduced relative to the value predicted for free sound propagation. A_{screen} can be calculated on the

basis of geometric quantities (height of the source, screen height, receiver height, distance between source and screen and between screen and receiver).

Apart from these damping attenuations, other influences also lead to level reductions. A level *increase* can be caused by the presence of reflecting barriers, an effect that can be calculated by the use of mirror sound sources.

The calculations are carried out in accordance with ISO/DIS 9613-2, generally in octave bands. It is common to use PC programs in performing calculations of this type. The following formula is useful for an approximate immission calculation:

$$L_A = L_{WA} - 27 \log d + 4\,\text{dB} \tag{44}$$

where

L_A = A-weighted sound-pressure level under downwind conditions
L_{WA} = A-weighted sound-power level of the sound source
d = distance (sound source – immission point) in m

This relationship is applicable to free sound propagation over an even surface in the absence of screening, and for the average octave spectrum shown in Figure 8.

7.3. Typical Sound Levels at the Workplace and Near an Industrial Complex

It is necessary to take modern acoustics into account during the technical planning phase of plant development. This is the only way of meeting acoustical requirements established by the responsible authorities (see Section 4) for sound immission limits both at the workplace and in the immediate neighborhood.

In new chemical plants equipped with state-of-the-art noise-control measures, sound-pressure levels exceeding 85 dB (A) under normal operating conditions are found only inside machinery structures and accessible enclosures. Outside the plant, sound-pressure levels should not exceed 80 dB (A).

With modern noise-control measures, the minimum distance between a plant boundary and an adjacent residential neighborhood required to meet an immission-level target of 45 dB (A) is ca. 500 m for a complex occupying 1 km^2, and ca. 350 m for a plant size of 0.3 km^2. These distances are sufficiently small to permit the resolution of acoustic problems related to protection of the neighborhood for most refineries and chemical or petrochemical plants (→ Oil Refining, Chap. 4.2.3.; → Iron, Chap. 4.3.).

Abstract

The article contains sections titled:

1. Introduction: Emissions due to the Chemical Industry
1.1. Greenhouse Gases
1.2. Nitrogen and Sulfur Oxides
1.3. Volatile Organic Compounds
1.4. Emission Inventories
2. Physics and Chemistry of the Atmosphere
2.1. Chemistry of the Atmosphere
2.1.1. Formation of the Primeval Atmosphere
2.1.2. Formation of the Present Atmosphere
2.1.3. Composition of the Present Atmosphere
2.1.4. Trace Gas Cycles
2.1.5. The Aerosol
2.2. Energetics of the Atmosphere

2.2.1. Solar Radiation
2.2.2. Infrared Radiation
2.2.3. Radiation Equilibrium
2.2.4. Energy Balance
2.3. Dynamics of the Atmosphere
2.3.1. Forces
2.3.2. Motions
2.3.3. Stability
2.4. Air-Pollution Control
2.4.1. Methods of Calculating the Dispersion of Pollution
2.4.1.1. Empirical Formulas
2.4.1.2. Gauss Formulas
2.4.1.3. Diffusion Equation
2.4.1.4. Stationary Solution of the Diffusion Equation
2.4.1.5. Particle Models
2.4.2. Use of the Diffusion Calculation
2.4.3. Environmental Compatibility and Simulation of the Environment
3. Effects of Air Pollutants
3.1. Effects on Humans
3.2. General Effects
3.2.1. Specific Pollutants
3.2.2. Persons Needing Special Protection
3.2.3. Carcinogenicity, Mutagenicity, and Teratogenicity
3.3. Environmentally Relevant Air Pollutants
3.3.1. Sulfur Dioxide
3.3.2. Nitrogen Oxides
3.3.3. Ozone
3.3.4. Carbon Monoxide
3.3.5. Dusts
3.3.6. Lead
3.3.7. Cadmium
3.3.8. Arsenic
3.3.9. Benzene
3.3.10. Polycyclic Aromatic Hydrocarbons
3.3.11. Diesel Motor Emissions
3.3.12. Dioxins and Furans
3.4. Effects on Plants
3.4.1. Relationship between Immission and Effect
3.4.2. Effect of Individual Pollutants
3.4.2.1. Sulfur Dioxide
3.4.2.2. Hydrogen Fluoride
3.4.2.3. Hydrogen Chloride and Chlorine
3.4.2.4. Nitrogen Dioxide and Ammonia
3.4.2.5. Hydrogen Sulfide
3.4.2.6. Ethylene
3.4.2.7. Ozone and Other Photooxidants
3.4.2.8. Dust
3.4.2.9. Acid Rain
4. Laws and Technical Regulations

1. Introduction: Emissions due to the Chemical Industry

John Wolf

1.1. Greenhouse Gases

The protection of the earth's atmosphere is one of the greatest environmental-political challenges worldwide. International agreements are needed to reduce man-made emissions and to introduce effective countermeasures. Precautionary measures on a national scale are certainly necessary, but alone are not sufficient to prevent the global changes to the earth's atmosphere that could result from the greenhouse effect or the ozone hole. Using the chemical industry as an example, the following chapters describe measures taken in Germany, and discuss the proportion of the total emissions for which the chemical industry is responsible.

The air — the natural mixture of gases that forms the earth's atmosphere — contains 78 % nitrogen and 21 % oxygen at sea level, excluding water vapor. The trace gases present in air are extremely important. Without them, the temperature at the earth's surface would be ca. – 18 °C.

Concentrations of these trace gases have been measured continuously only in recent times. The longest series of records is for carbon dioxide (CO_2). The continuous increase in CO_2 concentration since the beginning of industrialization over 200 years ago is shown in Figure 1. The growth rates for nonmethane hydrocarbons (NMHC), nitrogen oxides (NO_x), carbon monoxide (CO), methane (CH_4), dinitrogen oxide (N_2O), and ozone (O_3) are given in Table 1. As a result of the tendency of these concentrations to increase, some scientists have predicted a temperature increase of 3 – 5 °C, based on mathematical models. It might be thought that such a small temperature rise would not make any action necessary, as temperature changes have often been observed in the earth's history. The most recent change was a reduction of 6 °C following a temperate period, which led to an ice age. Today we are in a warm period, and a further temperature increase of 3 – 5 °C could change the precipitation distribution, shift climatic and vegetation zones, and hence contribute to an increase in climate-induced damage, degradative changes to the soil, and deterioration in the world food supply. The main contributors to this greenhouse effect are carbon dioxide (ca. 50 %), followed by methane (19 %) and the chlorofluorohydrocarbons (17 %). Other contributors include the ozone of the troposphere (ca. 8 %), nitrogen oxides (ca. 4 %), and stratospheric water vapor (ca. 2 %). The increase in the methane concentration is often directly related to the food requirements of the increasing world population (e.g., a byproduct of animal husbandry). The increase in CO_2 concentration correlates with the growth of energy production and traffic, associated with industrialization. The aim of German legislation is to reduce the energy-related emission of carbon dioxide by 25 % by the year 2005. The volume emitted during the year 1987 is the reference figure: emission from the pre-unification Federal Republic in 1987 was 726×10^6 t; total emission from the reunified Federal Republic in 1990 was 1031×10^6 t [1], [2].

Table 1. Mean global concentrations and rates of increase of the most important trace gases

Compound	Concentration, ppb	Rate of increase, %/a
CO_2	350×10^3	0.5
C_2H_6	1	0.8*
NO_x	very variable	1
CO	100	0.8*
CH_4	1640	1
N_2O	310	0.3

O_3	30	1*

* Increase observed in the northern hemisphere only.

Figure 1. Increase in the CO_2 content of the atmosphere

The main international agreement to reduce these man-made emissions is the United Nations Framework Convention on Climate Change (UNFCCC), adopted in New York on May 9, 1992. The ultimate objective of this convention is to achieve stabilization of greenhouse gas concentrations in the atmosphere at a level that would prevent dangerous anthropogenic interference with the climate system and to enable economic development in a sustainable matter. The conference of the Parties, as the supreme body of this convention, selected Bonn, Germany, to host the permanent secretariat of the Convention [13]. As of January 28, 1998 the Convention had received 174 instruments of ratification. In 1995 in Berlin, the UNFCCC member nations agreed to negotiate setting new commitments for limiting greenhouse gas emissions after the year 2000 for developed nations. The EU proposed a 7.5 % emission reduction by 2005 and a 15 % reduction from the 1990 level by 2010. Germany declared that it would reduce its 1990 CO_2 emissions by 25 % by 2005, which represents a further reduction relative to the initial decision made in 1990 [1]. In the third session of the conference of the parties, held in December, 1997, the Kyoto Protocol was adopted. In Kyoto the parties assured that their aggregate anthropogenic carbon dioxide equivalent emissions of greenhouse gases (CO_2, CH_4, N_2O, fluorohydrocarbons, perfluorocarbons, and SF_6) do not exceed their assigned amounts and will be reduced to at least 5 % below 1990 levels in the commitment period 2008 to 2012. As of 7 January 1999, 71 countries have signed the Kyoto Protocol.

The chemical industry will contribute to the reduction in CO_2 emissions by utilizing industrial waste heat, by increasing the efficiency of its fuel-fired equipment (and other energy-saving measures), and by rationalizing energy utilization by matching supply to demand. The German chemical industry committed itself to reducing its CO_2 emissions by the year 2005 to more than 30 % below 1990 levels, in line with the voluntary agreement reached within the industry in February 1996. The objective of this agreement is to fulfill the climate change Convention and outperform the target of the German Government. By 1997 the German chemical industry reduced the specific energy consumption to 22 % and the CO_2 emission to 26 % below 1990 levels. The improvement made from 1990 to 1994 is listed in the following (CO_2 emissions due to power generation in 10^6 t) [14]:

1990	67.8
1991	56.3
1992	51.4
1993	48.0
1994	45.2

In the year 2000, the CO_2 emission of the German chemical industry due to power generation will be reduced by 30 % below 1990 levels.

1.2. Nitrogen and Sulfur Oxides

Whereas the environmental consequences of increased CO_2 emission cannot at present be estimated exactly, information is available on the effect of atmospheric impurities which have accumulated in the past as a result of the limited technology then available for reducing emissions (see Chap. Effects of Air Pollutants). The environmental effects first became evident as damage to forests caused by acid rain [3].

A considerable proportion of the acid in acid rain is derived from nitrogen oxides (NO_x), most of which is produced by combustion processes in factories and internal combustion engines by oxidation of nitrogen in the fuel and combustion air. A relatively small proportion is produced in the production of nitric acid.

The emission of nitrogen oxides in the Federal Republic of Germany in 1990 was ca. 2.6×10^6 t in the 11 old Länder and ca. 550×10^3 t in the 5 new Länder [3], [4]. Oxidation of the sulfur in fuel during combustion processes gives rise to sulfur dioxide emissions, e.g., from sulfuric acid production, from natural gas desulfurization plants (Claus plants), and from oil refineries. The emission of sulfur dioxide in 1990 was ca. 10^6 t (old Federal Republic). The new Länder emitted 4.8×10^6 t SO_2. The corresponding emissions of carbon monoxide in 1990 were 9×10^6 t (3.8×10^6 t), and of airborne particulate 480×10^3 t (1.8×10^6 t) [5].

Nitrogen oxide emissions in Germany in 1994 were 2.2×10^6 t and sulfur dioxide emissions 2.9×10^6 t [15]. In 1995, the German chemical industry emitted 63.4×10^3 t of sulfur dioxide and 39.6×10^3 t of nitrogen oxides, which includes the emissions of the old and new Länder. In the former Democratic Republic, the emissions of sulfur dioxide by the chemical

industry were reduced by 74 %, and those of nitrogen oxides by 57 %.

1.3. Volatile Organic Compounds

Emissions of volatile organic compounds (VOCs) in 1995 were 2.1×10^6 t. About 40 % of this resulted from incomplete combustion in internal combustion engines, mainly in road and rail vehicles. Approximately 20 % of the VOCs are emitted during storage and handling, during the filling of vehicles, and by evaporation from vehicles.

The annual total emission of 31×10^3 t of benzene in 1994 is mainly (> 90 %) due to motor vehicles. The benzene content of gasoline for Otto engines is currently 1.7 – 2.5 vol %. The main use of benzene is in industrial chemistry for the synthesis of aromatic intermediates and cycloaliphatic compounds. Approximately 80 % of the benzene is used in the production of ethylbenzene and isopropylbenzene (cumene), and as a precursor for styrene, phenol, and cyclohexane, which is further processed to give intermediates for polyamide production.

Approximately 50 % of VOC emission results from the use of solvents, and nearly 40 % of this is emitted in the course of painting. Next in order of quantity come degreasing in the metal industry (8 %), printing (8 %), and adhesives (7 %). A high proportion of these emissions are of halogenated hydrocarbons (HHCs), especially the chlorinated hydrocarbons (CHCs) such as perchloroethylene, trichloroethylene, dichloromethane, and 1,1,1-trichloroethane. In 1991, a total of 259×10^3 t were produced, of which 202×10^3 t were exported. The main uses of CHCs are metal degreasing, solvents for adhesives, plastics processing, solvents in chemical syntheses, paint removal, and textile cleaning.

The use of CHC solvents decreased from 180×10^3 t in 1986 to 53×10^3 t in 1992 following the introduction of recycling systems. Increased use of recycled materials reduced consumption to 30×10^3 t by 1995. In Western Europe, total consumption of CHC solvents in 1990 was 600×10^3 t (510×10^3 t new material, 90×10^3 recycled material). In the EU, 75 % of all CHC solvents used are lost to the atmosphere, while the corresponding figure for Germany is 53 % owing to legal restrictions on emissions [6]. The possibilities of finding substitutes for these applications are limited, so that continued efforts are being directed to the improvement of waste-gas purification techniques.

Production of the following compounds was discontinued as early as the 1980s, mainly in order to reduce emissions of dioxin: trichlorophenol (TCP), 2,4,5-trichlorophenoxyacetic acid (2,4,5-T), pentachlorophenol (PCP), and polychlorinated biphenyls (PCB).

Other man-made greenhouse gases and compounds that contribute to the destruction of ozone in the stratosphere include the chlorofluorohydrocarbons (CFCs) and halons, both of which are products of the chemical industry. Fully halogenated CFCs are stable in the troposphere. However, they can also reach the stratosphere where they are photolytically cleaved by UV radiation. This produces free chlorine atoms which can break down the ozone in a catalytic chain reaction.

A detailed treatment of the photochemical reactions of these and other trace gases in the atmosphere can be found in Chapter Photochemical Degradation. As a result of the Montreal Protocol of 1987 and the follow-up London Conference of 1990, the production of carbon tetrachloride, fully halogenated CFCs, and halons is to cease worldwide by the year 2000 [16]. Production was discontinued in Germany in 1994 and in the EU in 1997. Production of hydrogen-containing CFCs, CH_3CCl_3, and CHF_2Cl will cease in the year 2005 [9]. In the meantime, emissions of hydrogen-containing CFCs in Germany will be much reduced as a result of voluntary agreements with the producers of expanded polystyrene foams for thermal insulation, who have committed themselves to producing these foams without HCFCs by January 2000. In most areas, suitable replacements for CFCs are available [6], [10]. CFCs have not been used since 1988 in hair sprays, deodorants, and other domestic aerosol spray dispensers. CFC-free medicaments are being developed to replace the 900 t of CFCs which are currently used in medical aerosol sprays (e.g., asthma sprays). Since mid-1994 household appliances in Germany have been produced without CFCs; propane – butane mixtures or fluorohydrocarbons (FHCs) are now used as refrigerants. The latter compounds (e.g., R 134 a, CH_2FCF_3) are more short-lived in the atmosphere because of their hydrogen content, and have lower ozone depletion potential (ODP). Pentane is a suitable substitute for producing foamed plastics.

Halons were mainly used in fire extinguishers and industrial fire-fighting equipment. They have now been replaced by CO_2, water, foam, and powder. In 1990, 80 683 t of CFCs were produced in the Federal Republic of Germany. The production of halons was discontinued in 1991.

Guidelines for the limitation of VOC emissions are being prepared in the EU. Also, solvent management plans will be set up. The above-mentioned EU Guidelines will considerably accelerate the conversion to low-solvent water-based paints or even solvent-free powder paints in the paint industry (annual production of paints in 1997: 1.99×10^6 t). The production of high-solids coatings was increased from 6.8×10^3 t (1990) to 31.4×10^3 t (1996). The corresponding production figures for low-solvent paints (the sum of powder, dispersion, electrophoretic, and high-solids paints) are 130×10^3 t (1990) and 186×10^3 t (1997). Meanwhile, the major German automobile manufacturers now have plants available for painting motor vehicles with water-based paints [11]. As halogenated hydrocarbons are not used in these plants, VOC emissions have been considerably reduced. Initial tests show that medium-sized and small automobile painting and repair workshops, numbering around 12 000, can also use water-based paints. In any case, it should be possible to reduce the emission of organic solvents by up to 70 %. The printing and paper industries, which emit ca. 60×10^3 t VOCs (mainly hydrocarbons) could also make a considerable contribution to the planned reduction in emissions by changing to cleaning agents of vegetable origin, (e.g., in offset printing) and by finding substitutes for the solvent-containing paints and adhesives used in finishing processes.

In these and many other cases, further reductions in the emission of hydrocarbon solvents will be achieved by the use of substitute materials or by minimizing the solvent content of products rather than by improving waste-gas cleaning

technology, which can only be considered as secondary or end-of-the-pipe technology.

Approximately 26 × 10^3 t VOCs were emitted in 1995 by chemical plants [12], mainly during the production of plastics, rubber, pharmaceuticals, dyes, paints, solvents, and adhesives.

1.4. Emission Inventories

The European Environment Agency (EEA) was launched by the EU in 1993 and is based in Copenhagen, Denmark. It has a mandate defined by Council Regulation (EEC) No. 1210/90 to ensure the supply of objective, reliable, and comprehensive information at the European level. One task is to work on air pollution related problems [17], [18]. The Cooperative Programme for Monitoring and Evaluation of the Long Range Transmission of Air pollutants in Europe (EMEP) formed by a Protocol under the Long Range Transboundary Air Pollution Convention has established task forces to develop guidelines for the estimation and reporting of emission data. The UNECE Task Force on Emission Inventories (TFEI) will work out an Atmospheric Emission Inventory Guidebook, which will give quantitative information on emissions to the atmosphere by industrial processes, power plants, refineries, chemical plants, and other sources. The draft of this Guidebook is available on the Internet [19]. The final official version will be published on the website of the EEA [17].

The emissions due to the German chemical industry for 1979 – 1990 and 1995 are listed in Table 2 [12]. These data refer to the 11 Länder of the pre-unification Federal Republic. Comparable data from the Democratic Republic for this period are not available. The following data on emissions have been published by the new Länder for the year of reunification (1990): sulfur dioxide 460 × 10^3 t, nitrogen oxides 35 × 10^3 t, carbon monoxide 25 × 10^3 t, airborne particulates 150 × 10^3 t, and VOCs 90 × 10^3 t.

Table 2. Emissions from the German chemical industry in 10^3 t (1979 – 1995)

	1979	1981	1983	1984	1985	1986	1987	1988	1989	1990	1995
SO_2	178.0	158.5	131.0	125.0	111.0	104.0	101.0	91.0	71.0	56.0	65.4
NO_2	114.0	105.0	91.5	89.5	88.0	85.0	80.0	69.0	63.5	52.0	39.6
Dust	27.5	18.0	15.5	14.5	13.0	11.0	9.0	7.5	6.5	6.5	
CO	92.0	60.5	51.0	43.0	44.5	47.0	47.5	56.0	54.5	57.5	
VOCs	76.0	57.5	41.5	34.0	31.5	30.5	20.5	21.0	27.0	25.5	25.9

Unfortunately, it has not been possible to obtain comparable data for the emissions due to the chemical industries of other European countries.

Table 2 shows that there has been a drastic reduction in the pollutants emitted into the atmosphere by the chemical industry (pre-unification Federal Republic), which on average accounts for less than 3 % of total air pollution. This success is due in large measure to the changes brought about by the TA Luft 1986 (see Chap. Effects of Air Pollutants) [7], which has led to an extensive reorganization of the regulations for the control of emissions, and to the updating of the waste gas cleaning technology to correspond to the current state of the art. The TA Luft states that all old plants must be provided with state-of-the-art waste gas cleaning equipment within eight years. Similar regulations (Großfeuerungsanlagenverordnung, 13. BImSchV), were implemented in 1986 for power stations (flue-gas purification, especially by desulfurization and removal of nitrogen compounds). These regulations applied to a total of ca. 50 000 installations.

The costs of environmental protection were correspondingly large, accounting for an average of 15 % of the total investment in chemical plants. Of these costs, ca. 40 % are for air purification [8]. From 1987 to 1996 the German chemical industry invested € 7 × 10^9 in environmental protection equipment.

Since ca. 1970, the German chemical industry has increased its production by ca. 200 %, while at the same time emissions of air pollutants have been reduced by over two-thirds. This shows that industrial growth and the conservation of the environment need not be in conflict with each other. The following chapters consider which techniques can be used (Chap. Flue-Gas Purification in the Incineration of Hazardous Waste) and the legal measures necessary to achieve the desired standard of environmental protection.

2. Physics and Chemistry of the Atmosphere

Gerhard Manier

2.1. Chemistry of the Atmosphere

2.1.1. *Formation of the Primeval Atmosphere*

The primeval atmosphere was formed by the evolution of gas from the molten planet earth. As oxygen was chemically combined, the gases of this first atmosphere must have been largely in reduced form. The atmosphere consisted mainly of methane, with some ammonia, hydrogen, and water. In the molten planet, a gigantic blast furnace process started, in which nickel and iron oxides were reduced to nickel and iron. These components eventually formed the earth's core. Oxygen was liberated and increased the degree of oxidation of the earth's mantle and of the outgassed substances. The atmosphere then contained water vapor, carbon dioxide, and nitrogen. It is possible that this atmosphere had the same

composition as the gases produced today by volcanic action, which have the following composition:

H_2O	80 %
CO_2	10 %
H_2S	7 %
H_2	0.5 %
CO	0.5 %
CH_4 and NH_3 traces	

2.1.2. *Formation of the Present Atmosphere*

The present atmosphere was formed along with the hydrosphere, lithosphere, and biosphere. This can be envisaged as follows:

The earth cooled by radiating energy into space. The upper layers of the atmosphere became cool enough to be supersaturated with water vapor, and clouds formed. Droplets that were formed in the clouds led to raindrops. The rain did not yet reach the earth's surface, but vaporized in the lower atmosphere, which was still very hot. The water vapor so formed was carried back to high altitude by convection currents, where it again condensed to form clouds. Rain formed, and again fell back into the lower levels of the atmosphere and evaporated.

This water cycle was associated with a very large transfer of energy, as the heat needed to evaporate the water in the lower levels of the atmosphere was later liberated in the upper levels by condensation to form clouds. This is known as latent heat flow, as the heat is latent in the water vapor transported upwards. This latent heat flow led to further radiative cooling. After ca. 100 000 years, the rain reached the earth's surface, and a period of rain began which lasted ca. 40 000 years. Initially, the rain evaporated immediately at the earth's surface. In the course of time, the earth's surface cooled more and more, so that liquid water collected in the deeper regions, eventually forming the hydrosphere. The rain washed carbon dioxide out of the atmosphere, forming the carbonate sediments of the lithosphere in the seas.

A precondition for the formation of the biosphere was the presence of oxygen in the atmosphere.

The oxygen was formed by plants according to the following equation:

$$6\,CO_2 + 6\,H_2O + \text{light} + \text{chlorophyll} _ C_6H_{12}O_6 + 6\,O_2$$

This process is known as assimilation. At the same time, plant respiration and decay of the plant mass convert oxygen into carbon dioxide. A continuous increase in the oxygen content of the atmosphere can only happen if part of the plant mass does not decay, but is preserved with exclusion of air (i.e., forms sediments). It has been calculated that 1×10^{22} g organic carbon—the amount of carbon preserved with exclusion of air— corresponds to 2.7×10^{22} g oxygen. This is 20 times the amount present in the atmosphere today. The difference was consumed in oxidizing the earth's crust and the primeval atmosphere.

The chronology of these events was probably as follows:

The first appearance of cells in an oxygen-free environment (energy gain by fermentation processes) occurred 4×10^9 years ago.

The first oxygen was produced in water (2 – 3) $\times 10^9$ years ago at a depth great enough to avoid damage to the organisms by UV radiation from the sun, but with adequate availability of light. Part of this oxygen was released from the ocean into the atmosphere and formed the ozone layer. Part of the UV radiation was absorbed by this ozone layer, and life formation moved closer to the surface of the water, the oxygen content of the atmosphere increased, and the ozone layer grew. The ozone layer protected the earth from the UV radiation of the sun to an ever-increasing extent, until eventually life became possible on land. This process was complete ca. 600×10^6 years ago.

2.1.3. *Composition of the Present Atmosphere*

It is convenient to consider the composition of the atmosphere in three parts:

1. Dry air
2. Water in all three states of aggregation
3. Atmospheric aerosol

Composition of the Dry Atmosphere (Table 3). Nitrogen and oxygen together account for >99 % of the atmosphere. If the noble gas argon is included, this figure becomes 99.96 %.

Table 3. Composition of the dry atmosphere [20]

Component	Concentration	Probable residence time in the atmosphere

Principal components		
N_2	78.09 %	2×10^7 a
O_2	20.95 %	
Ar	0.93 %	
CO_2	0.033 %	5 – 10 a
Other components (*constant concentration*)		
Ne	18 ppm	
He	5 ppm	3×10^6 a
Kr	1 ppm	
Xe	0.09 ppm	
CH_4	1.5 ppm	3 a
CO	0.1 ppm	0.35 a
H_2	0.5 ppm	
N_2O	0.25 ppm	<200 a
Other components (*variable concentration*)		
O_3	≤10 ppm (stratosphere)	
	5 – 50 ppb (pure air)	
	≤500 ppb (polluted air near ground)	
H_2S	0.2 ppb (over land)	10 d
SO_2	0.2 ppb (over land)	5 d
NH_3	6 ppb (over land)	1 – 4 d
NO_2	1 ppb (over land)	2 – 8 d
	100 ppb (polluted air near ground)	
CH_2O	0 – 10 ppb	

The carbon dioxide is present at a much lower concentration which varies somewhat, especially close to the surface. If the carbon dioxide is added to the above three gases, the total then accounts for 99.997 % of the dry atmosphere. The small remainder of 0.003 % (30 ppm) is nevertheless extremely important, and includes both highly aggressive gases and gases upon whose presence the very existence of life earth depends, such as ozone. The concentrations of some of these gases can fluctuate considerably.

Variation in Composition with Altitude. If there is a concentration gradient within a given volume of a gas, Brownian motion and diffusion of the gas eventually lead to a uniform spatial distribution. In addition, the gases in the atmosphere are subject to gravitational acceleration towards the earth's center. In the equilibrium state, this force is compensated by a pressure gradient force acting upwards. This force results from the decrease in air pressure with altitude. The partial pressure of a light gas decreases more slowly with altitude than that of a dense gas, a phenomenon known as segregation.

For example, the light gas helium (relative molecular mass 4 g/mol) is present at the earth's surface at a partial pressure of 5.24×10^{-3} hPa. The other air components (mean relative molecular mass 29 g/mol) have a total partial pressure at the earth's surface of 1000 hPa. At an altitude of 113 km, the partial pressures of the helium and of the other air components might be expected to be identical, but this is not the case. Measurements have shown that the composition remains constant in the lower 80 – 100 km, but above 100 km the concentration of the helium decreases less rapidly than that of the heavier constituents of the atmosphere. Segregation in the lower atmospheric region is prevented by other mechanisms, mainly turbulent mixing of the atmosphere by rising and falling air streams. This region, in which the composition of the atmosphere is constant, is named the homosphere, and extends to an altitude of ca. 100 km. In the overlying atmospheric layers, the concentration of the light gases decreases more slowly with altitude than those of the heavy gases, and segregation takes place. The topmost layer of the atmosphere consists almost entirely of hydrogen and helium. The atmosphere above 100 km is known as the heterosphere.

The Ozone Layer. At an altitude of 20 – 30 km, there is a layer in which the concentration of ozone is very high. There are several reactions that lead to the formation and destruction of atomic oxygen and ozone [21].

$$O_2 + h\nu \rightarrow 2O \quad (1)$$

$$O_3 + h\nu \rightarrow O_2 + O \quad (2)$$

These are the primary photochemical reactions. Equation (1) represents cleavage of the oxygen molecule into two oxygen atoms by UV radiation. In Equation (2), the action of radiation up to the IR range of the solar spectrum on an ozone molecule leads to formation of an oxygen molecule and an oxygen atom. Two further, secondary reactions are involved in the formation and destruction of ozone.

$$O + O_2 + M \rightarrow O_3 + M \quad (3)$$

$$O + O_3 \rightarrow 2\,O_2 \quad (4)$$

In Equation (3), a neutral collision partner M must be present to remove the excess energy and momentum liberated by ozone formation.

The probability of a particular reaction taking place depends on the available radiation and the density of the atmosphere. Both of these parameters vary with altitude, the density decreasing, and the radiation increasing with increasing altitude. As these two parameters have opposite effects, there is an altitude at which the ozone concentration is a maximum. This altitude can be calculated, and is ca. 20 km at a latitude of 10° N. At higher latitudes, the maximum is displaced upwards and the concentration decreases. Measurements have shown that at lower latitudes the calculated concentrations are considerably higher than the measured concentrations. At higher latitudes, the measured concentrations are greater and occur at lower altitudes than calculations predict. These differences between measured and calculated values can only be explained by transport of ozone from lower to higher latitudes. Human activities (e.g., CFC production, air traffic) increase the concentration of nitrogen and chlorine radicals (NO_x and ClO_x) in the stratosphere. Both substances lead to ozone destruction, but because the individual reaction cycles are interlinked and extremely complex, the prediction of future changes in the ozone layer is difficult [21].

Uppermost Layers of the Atmosphere. Above 500 km, the atomic forms of the atmospheric gases dominate, and above 1000 km, the light atoms helium and hydrogen are virtually the only species present. Moreover, above 500 km, the mean free path between collisions becomes so large that the particles follow ballistic trajectories. This is known as the spray region, and the atmospheric region is known as the exosphere. When the individual atoms follow ballistic trajectories, they can overcome the attraction of the earth and escape into space. Only hydrogen can reach the escape velocity of 12 km/s to an appreciable extent, so that the amount of hydrogen in the atmosphere is very small. Hydrogen is produced by the dissociation of water vapor. The probability of escape of an oxygen atom is very low, so that it can be assumed that all the oxygen formed on the earth is still present.

2.1.4. *Trace Gas Cycles*

Sulfur Cycle. The following sulfur compounds are present in the atmosphere: H_2S, SO_2, SO_3, and SO_4^{2-}.

All these compounds are chemically reactive. There is a link to the water (hydrological) cycle. Their residence times are short, so that their concentrations can show very large spatial and time-dependent variations.

The most important natural source is the bacterial degradation of organic substances in coastal regions and marshy areas, forming hydrogen sulfide (ca. 32×10^{12} g/a, as sulfur). High wind speeds and the breaking of ocean waves lead to the formation of small water droplets which then evaporate, leaving behind salt (NaCl) as the main component. Sulfates (44×10^{12} g/a) are also formed. Volcanic activity causes the transport of 3×10^{12} g/a S into the atmosphere, mainly as H_2S and SO_2. The most important man-made source of sulfur compounds is the burning of coal and mineral oil, which forms sulfur dioxide (65×10^{12} g/a).

The most important sink for the sulfur dioxide and sulfates is wet deposition (106×10^{12} g/a) by the atmospheric processes of washout and rainout. Gases and sulfate can dissolve in raindrops and be transported back to the earth's surface, a process known as washout. The condensation nuclei from which cloud droplets are formed, and which can then become raindrops, contain gases and sulfates. This process is known as rainout.

In addition to wet deposition, dry deposition of sulfates and sulfur dioxide on plants and on the surface of the earth or water (3.8×10^{13} g/a) can occur. The total turnover of sulfur, is 144×10^{12} g/a.

Nitrogen Cycle. The nitrogen molecule is the main constituent of the atmosphere. Nitrogen is chemically unreactive, and its contribution to the nitrogen compounds cycle is of minor importance, due to the enormous size of the reservoir.

Dinitrogen oxide, N_2O, has a long residence time in the atmosphere. It is formed by the reduction of nitrates and nitrites by bacteria in the soil. The compound probably disappears by photochemical dissociation:

$$N_2O + h\nu \rightarrow N_2 + O$$

There is no link to the other nitrogen cycles. N_2O takes part in catalytic ozone degradation reactions.

Ammonia and its compounds are chemically reactive. There is a link to the water cycle. Because the residence time of these gases in the atmosphere is short, the concentration can show large spatial and time-dependent variations.

The main source is the degradation of organic substances in the soil. Figures for the amount (as nitrogen) that enters the atmosphere fluctuate considerably [$(113 – 244) \times 10^{12}$ g/a]. Dry and wet deposition carry NH_3 back to the earth's surface. Reactions with water vapor, sulfur dioxide, and carbon dioxide can form ammonium sulfate or ammonium bicarbonate as aerosol particles. A small sink for ammonia is provided by the reaction with the radical ·OH, which forms NO_x and water. This represents the only link between the ammonia cycle and the NO_x cycle.

Nitrogen oxides, NO_x are chemically reactive. There is a link to the water cycle. The residence time in the atmosphere is short, and the concentrations can therefore show very large spatial and time-dependent variations. The most important

substances are nitrogen monoxide (NO) and nitrogen dioxide (NO_2). Other compounds include dinitrogen trioxide (N_2O_3), nitrous acid (HNO_2), dinitrogen pentoxide (N_2O_5), nitric acid (HNO_3), nitrites (NO_2^-) and nitrates (NO_3^-). The nitrates have the highest oxidation state, and are therefore the stable final state after the reaction of NO via NO_2 to form NO_3^-. Each oxidation step occurs by reaction with ozone (O_3).

The main sources of nitrogen oxides are bacterial nitrate degradation in the soil (2.1 – 8.9 × 10^{13} g/a) and the combustion of oil in industry and by motor vehicles (19 × 10^{12} g/a). Further sources are the link to the ammonia cycle and the formation of nitrogen oxides by lightning. Organic nitrogen compounds are very important in the soil and in the ocean, but they can be harmful constituents of the atmosphere.

Carbon Cycle. Four atmospheric carbon cycles exist, involving the substances CO_2, CO, CH_4, and other carbon compounds.

Carbon dioxide is one of the most important constituents of the atmosphere. It has a long residence time. The main sources are the combustion of coal, the respiration of living organism, and the degradation of organic substances. The main sink is photosynthesis, a further sink being the dissolution of carbon dioxide in the oceans and formation of calcium carbonate sediments. The carbon dioxide content of the atmosphere increases by ca. 0.75 ppm annually.

The greenhouse effect of the atmosphere (solar radiation passes through, thermal radiation is retained) depends on the concentrations of water vapor and carbon dioxide. Therefore, an increase in the carbon dioxide content can lead to a change in the greenhouse effect, and hence to climatic change. However, because these processes are extremely complex, predictions are difficult [22].

Carbon monoxide can be oxidized to carbon dioxide, but this reaction does not proceed in the atmosphere, so that CO has a relatively long residence time. Sources of carbon monoxide include incomplete combustion and generation by microorganisms on the surface of the ocean. Bacteria in soil consume carbon monoxide. It also reacts with ·OH radicals. Carbon monoxide concentrations can show very large spatial and time-dependent variations, especially in towns.

Methane is a relatively common gas and has low chemical reactivity. It is produced and consumed as part of the biological cycle. Its concentration is presently increasing by ca. 1.5 %/a. Reaction with oxygen in the stratosphere leads to the formation of the methyl radical and ·OH, which also contributes to catalytic ozone breakdown. Methane also contributes to the greenhouse effect.

Water Cycle. The total mass of water on the earth is 1.36 × 10^{21} kg, corresponding to 2.66 × 10^6 kg water per m^2, or a layer of water 2660 m thick. Of this water, 97 % is contained in the oceans, and 2.3 % in ice. Subterranean water (groundwater) accounts for 0.7 %, and lakes and rivers 0.01 %. The atmosphere contains 0.001 % or 26.6 kg/m^2. This amount of water corresponds to a depth of 2.66 cm. As the average annual precipitation is 857 mm, and only 26.6 mm is present in the atmosphere, the equivalent of the total atmospheric water content must be deposited on the earth's surface in 10 d to give the above mean annual precipitation figure, i.e., the cycle time of the water in the atmosphere is 10 d. The water cycle causes cleansing of the atmosphere, as all substances are eventually converted to water-soluble products and return to the earth's surface with the rain. Evaporation produces only water vapor.

2.1.5. *The Aerosol*

The atmosphere contains particles as well as gaseous components. These particles are much larger than single molecules, but are still so small that their settling rate is generally negligible. Their size varies between 5 × 10^{-3} and 20 µm, and their number density between 10^2 and 10^6 cm^{-3}. Particles with a radius of 0.1 µm are especially abundant. Particles larger than 10 µm are extremely rare, as their settling rate is so great that they become deposited on the earth's surface close to their source. Very small particles also do not occur, because they agglomerate rapidly to form larger particles.

Sources and Chemical Composition of the Aerosol. There are four mechanisms by which aerosols are produced:

1. Combustion (industrial combustion, forest fires, traffic), forming salts, carbonates, and lead.
2. Reactions in the gas phase (sulfur and nitrogen cycle) to form sulfates and nitrates.
3. Whirling up of solid material, whereby silicates and salts of calcium, potassium, and sodium enter the atmosphere.
4. Whirling up of liquid. At high wind speeds, air bubbles form on the ocean. When these bubbles burst, many small water droplets are formed. These then evaporate, leaving salt as an aerosol.

Sinks for the Aerosol. Large particles leave the atmosphere owing to their high rate of settling, becoming deposited preferentially on vegetation. Larger particles are also washed out of the atmosphere by rain.

The residence time of large particles (>10 µm) amounts to minutes or hours. Particles of 2 –10 µm have a residence time of hours or days, and those of 0.1 µm a residence time of several days. Particles smaller than 0.05 µm agglomerate to form larger particles and have a short residence time (< 1 h).

Effect of Altitude on Aerosol Concentration. In the lowest 5 km, the concentration of the aerosol decreases much more rapidly than that of the other atmospheric constituents. Whereas the altitude of the homogeneous atmosphere is 8 km, it is found that a hazy atmosphere is homogeneous to an altitude of 3 km. (The altitude of a homogeneous atmosphere is that for which the density of the air or of the aerosol, independent of the altitude, is equal to the density at the earth's surface.) Above an altitude of 5 km, the aerosol behaves like air, i.e., the densities decrease at the same rate. Between 20 and 30 km, the aerosol concentration remains constant. Aerosol particles are produced in this region.

2.2. Energetics of the Atmosphere

2.2.1. *Solar Radiation*

The sun is the sole source of energy for all processes on the earth. At the upper limit of the atmosphere, the radiation flux density is 1376 W/m^2. This radiation is attenuated in the atmosphere by scattering and absorption caused by air molecules, certain gases, the aerosol, and clouds.

Attenuation by the gases is proportional to λ^{-4}. With increasing path length through the atmosphere, the energy maximum shifts from the blue to the red region. One consequence of this is the red appearance of the sun at sunrise and sunset.

The aerosol also attenuates the shorter wavelengths more strongly than the longer (~ λ^{-1}). Different particle size distributions of the aerosol can lead to very different directional distributions of the scattered radiation. Forward scattering dominates, in contrast to scattering by air molecules.

The absorption of solar radiation by gases leads to excitation. Owing to the high density of the air, the collision number is so large that the energy of excitation can be transferred as kinetic energy to other air molecules. This leads to an increase in the temperature of the gas. Thus, unlike scattering, absorption leads to the transformation of radiant energy into thermal energy.

The nitrogen molecules and the oxygen atoms or molecules absorb UV radiation (<200 nm) even at high altitudes. Ozone absorbs at wavelengths of <300 nm, so that radiation in this range does not reach the earth's surface. Ozone absorbs only weakly in the visible region. Water vapor absorbs in the infrared.

Even a thin cloud layer prevents the sun from being visible, i.e., direct solar radiation is zero.

Part of the direct solar radiation is absorbed at the earth's surface. The energy yield increases with the altitude of the sun and also with increasing darkness of the earth's surface. Forests and water surfaces are very dark, while snow has the brightest surface.

Diffuse solar radiation is produced by scattering of direct solar radiation by air molecules and the aerosol. The sum of the direct and diffuse solar radiation is the global radiation. In the following, some values of the global radiation F_G for a cloudless sky at various zenith angles ζ (measurements were carried out in Frankfurt/Main, Germany) are given:

ζ,	30°	40°	50°	60°	70°	80°
F_G, W/m^2	963	830	670	481	293	119

If the sky is completely covered with clouds, the following percentages of the global radiation of a cloudless sky are obtained:

Fog	15 %
Rain clouds	19 %
Low clouds	25 – 33 %
Medium altitude clouds	40 – 50 %
High ice clouds	80 %

2.2.2. *Infrared Radiation*

All bodies whose temperature is above absolute zero emit radiation. In the atmosphere, these includes the following emitters: the earth's surface, clouds, water vapor, and carbon dioxide.

The earth's surface and clouds radiate like black bodies, i.e., the radiation flux density F depends on the surface temperature T and the longwave emissivity ϵ of the material and is given by:

$$F = \varepsilon \times 5.67 \times 10^{-8} \times T^4$$

For most surfaces, ϵ lies between 0.92 and 0.98.

Unlike solid or liquid bodies, gases do not radiate at all in certain wavelength ranges, and radiate like a black body in other ranges.

2.2.3. *Radiation Equilibrium*

It can be assumed that the planet earth is in thermal equilibrium. Thus, the absorbed short-wave radiation from the sun is equal to the long wave radiation emitted from the earth. In the absence of an atmosphere, this would occur if the earth's surface temperature were – 21 °C. But the average temperature of the earth's surface is + 14.3 °C, and a temperature of – 21 °C is found at an altitude of ca. 6 km. This altitude corresponds to the average altitude of the upper surface of the clouds. The atmosphere and the clouds provide effective protection from radiation. This is also known as the greenhouse effect, whereby shortwave radiation is allowed to reach the earth, while water vapor, carbon dioxide, aerosol, and clouds only allow the partial transmission of long-wave radiation.

2.2.4. *Energy Balance*

The radiation balance of the earth's surface is positive, and that of the atmosphere negative. The energy balances of the earth and the atmosphere are evened out by the turbulent flows of sensible and latent heat.

A turbulent transport process, whether of temperature, water vapor, or pollutants can be pictured as follows: The air flow is split up into several densely packed flow filaments. In each flow filament, the mean flow rate, temperature, water vapor content, and concentration of pollutants is constant. There are differences between the individual flow filaments. In a turbulent flow, there is an intensive exchange of air parcels between the individual flow filaments. These air parcels transfer the property of one flow filament into another. If there is a temperature difference between the two flow filaments, this exchange of air parcels implies a transfer of heat. The transfer is always in such a direction that temperature differences are evened out. The same considerations also apply to water vapor (latent heat flow) or any other substance.

If we consider the effect of geographical latitude on the energy balance, there is a surplus at the lower latitudes, while, at high latitudes where the sun does not shine for a large part of the year or the angle of incidence of the solar radiation is low even in summer, the energy balance is negative. As the temperature does not increase continuously in the lower latitudes or decrease continuously in the polar regions, there must be a transfer of energy from the lower latitudes to the higher. This transfer exhibits a maximum in the geographical latitude at which the energy balance is zero. This is the case at a latitude of ca. 40° N or 40° S. At this latitude, the energy transferred must be 4.2×10^{15} W. This transfer takes place as a result of normal weather processes, in high latitudes by the interchange of low- and high-pressure areas, and in low latitudes by the circulation of trade winds.

2.3. Dynamics of the Atmosphere

2.3.1. *Forces*

Five forces act in the atmosphere and determine wind flows.

The gravitational force causes all objects, including the air, to accelerate towards the center of the earth.

The pressure gradient force operates wherever pressure differences exist. It accelerates the air from high- to low-pressure regions. In the vertical direction, it opposes the gravitational force.

The Coriolis force is an apparent force that must be introduced because the air movements are observed on a rotating earth. The Coriolis force diverts flows to the right in the northern hemisphere, and is proportional to the flow rate.

The centrifugal force acts in an outwards direction on curved flow paths (e.g., low-pressure areas or tornadoes). It is proportional to the square of the flow rate, and is inversely proportional to the radius of the flow path.

The frictional force is always present if there is a spatial change in flow rate, as is always the case in the vicinity of the earth's surface. The frictional force is in the opposite direction to the direction of the flow and its magnitude increases with increasing flow rate and with decreasing stability of the atmosphere (see also Section Stability.)

2.3.2. *Motions*

There is very often an equilibrium between two or three forces in the atmosphere, with the other forces being of minor importance. (This is true even though continuously observable changes in the flow pattern can only be explained by nonequilibrium conditions.) In the free atmosphere, pressure gradient forces and Coriolis forces dominate. In the equilibrium condition, flow takes place parallel to the isobars (lines of equal atmospheric pressure). In the northern hemisphere the winds in low-pressure regions rotate anticlockwise, and in high-pressure areas the rotation is clockwise.

Close to the earth's surface, the frictional force is also important.

Two different layers close to the earth's surface can be distinguished. In the lower (Prandtl) layer, which extends to a height of ca. 100 m, the wind velocity increases with altitude, but the wind direction remains constant. In the overlying layer, planetary boundary layer, which can reach an height of 1500 m, the wind velocity increases further and the wind direction changes.

The variation of wind speed with height in the Prandtl layer over a land surface with constant roughness can be expressed by the following equation:

$$\bar{u}(z) = u^*/\varkappa[\ln(z/z_0)] - \psi(z/L)$$

$\bar{u}$ = mean wind speed, z = altitude coordinate, u^* = friction velocity, $\varkappa$ = 0.4, z_0 = roughness height, Ψ = stability function, L = Monin – Obukhov length.

Disregarding the stability function, the flow rate varies with the logarithm of the altitude. At the roughness height ($z = z_0$), the velocity is zero. z_0 depends on the height of the roughness elements. It varies from a few millimeters over ice and water surfaces to several meters over large towns and forests. The friction velocity u^* represents the effect of friction. u^* is ca. $0.1 \times \bar{u}$ (10 m). The stability function represents the change with height as a function of the stability of the layer (see Section Stability). For a stable layer, the function is <0, and for an unstable layer >0.

The flow direction in the Prandtl layer deviates from the direction of the ground flow at the top of the planetary boundary layer. There is a shift to the left, which increases with increasing roughness and stability (the extent of shift being 10 – 40°). At the top of the planetary boundary layer, the wind vector changes into the equilibrium flow resulting from the pressure gradient force and the Coriolis force. That is, with increasing height in the planetary boundary layer, the wind

rotates towards the right and the velocity increases.

Deviations from the ideal conditions (flat surface and constant roughness) can lead to considerable changes in the wind field.

For very large ground roughness values (e.g., in large towns or forests) the wind speed does not become zero at height z_0, but at greater heights. A zero point shift, ($z = z + d_0$) must be introduced. The zero point shift d_0 is somewhat less than the mean height of the obstructions.

The flow is very strongly deviated by topographical obstructions. The deviation depends on the orientation of the topographical structures relative to the ground flow (flow at the top of the planetary boundary layer). In valleys, the flow is channeled in the direction of the axis of the valley, independent of the direction of the ground flow. The channeling effect becomes greater as the depth of the valley increases, but even very wide valleys such as the Rhine valley at Ludwigshafen, Germany (width ca. 30 km, height of sides ca. 300 m) cause channeling of the flow. The wind speed at the base of the valley is lower for larger differences between the ground flow direction and the valley direction. The air preferably flows around individual high and steep mountains, but goes over the top of wide high ridges. In basins, the flow rate is significantly lower, and in open locations on mountains it is higher than over flat terrain.

Single buildings modify the flow considerably. On the side facing the wind, a ground eddy forms with a horizontal axis and a countercurrent flow near ground level. A disturbed region also forms on the downwind side, i.e., an eddy with a horizontal axis and a countercurrent flow at ground level. Further downwind, the flow changes back to the undisturbed state. The distance to which this disturbance extends in the flow direction can be many times the height of the building. Undisturbed flow is reestablished at a distance equal to 100 times the height of the building [23].

In streets, an eddy is produced whose intensity increases as the ground flow component perpendicular to the street increases.

The flow field in cities and industrial areas is extremely complex owing to the complexity of the configurations of the buildings.

Flow fields of this kind cannot be adequately understood by measurements in the field. Wind tunnel tests [23] or mathematical models [24] must be used. An example of the mathematical modeling of the wind field in a city area is shown in Figure 2.

Figure 2. Calculated wind field 1.5 m height in a city area for undisturbed flow at 60°, showing 10-s trajectories

2.3.3. *Stability*

Thermodynamics plays a part in many atmospheric processes. This is very important in the suppression or production of vertical movement. The most spectacular manifestation of this is a thunderstorm, in which intense vertical movements of the air are a characteristic feature. On clear nights, the thin clusters of very long, meandering smoke trails that can be observed owe their existence to a much diminished vertical movement.

In each case, the vertical temperature gradient is decisive. Normally, the decrease in temperature with altitude is 0.7 °C/100 m. On cloudless nights, reversal of the temperature gradient occurs such that the temperature can increase by several degrees per 100 m (inversion). On sunny days and during the summer months the temperature decrease can be > 1 °C/100 m.

These temperature changes in the atmosphere can be compared to the temperature changes experienced by a parcel of air that is ideally thermally isolated from its surroundings, and either rises or falls like a body floating in a liquid. The temperature change of the air parcel can be deduced from the First Law of Thermodynamics, which gives a temperature decrease of 1 °C for a 100 m ascent, and an equal temperature increase if the air parcel sinks by 100 m. In the normal case, the rising air parcel is colder and hence heavier than its surroundings. As it is heavier, it accelerates downwards, back to the starting level. The air parcel that has sunk is warmer than its surroundings and hence lighter, so that it accelerates upwards, again towards the starting level. Thus, vertical movements involving organized flows (e.g., upward moving or “anabatic” winds) or turbulence are damped, i.e., the layer is stable. The layer is especially stable if temperature increases with altitude (inversion).

If the temperature decrease in the atmosphere is > 1 °C/100 m the temperature of the air parcel above the starting level is higher than that of its surroundings. It is therefore lighter and becomes accelerated upwards, away from the starting level. This also holds when an organized or accidental displacement in a downwards direction occurs. Thus, vertical movements are amplified, and the layer is unstable.

The effect of stability or instability on the turbulence of the flow is especially relevant to the dilution of harmful substances in the atmosphere (see Section Air-Pollution Control). With turbulent fluctuations, momentum is also transferred, and this transfer determines the friction of the flow. Hence, the friction is greater for unstable layers, and the wind profile has a different form (see Section Motions).

Measures of stability are, e.g., the Richardson number, the Monin – Obukhov stability length, and stability classes.

The Richardson number *Ri* is defined as [25]:

$$Ri = \frac{g}{\bar{\Theta}} \frac{\partial\bar{\Theta}/\partial z}{(\partial\bar{u}/\partial z)^2}$$

where *g* = gravitational acceleration, $\bar{\Theta}$ = potential temperature.

It is a dimensionless number that represents the ratio of buoyancy to frictional forces.

The Monin – Obukhov stability length *L* is defined as [26]:

$$L = \frac{T}{g} \frac{u_*^3}{\overline{w'T'}x}$$

where T is the temperature of the air in Kelvin, *w′* the turbulent fluctuation of the vertical velocity, *T′* the turbulent fluctuation in temperature, and $\overline{w'T'}$ he turbulent heat transfer.

This number also represents the ratio of the frictional forces to the buoyancy. Its dimension is length.

The Richardson number and the Monin – Obukhov stability length are negative for unstable layers and positive for stable layers.

The formerly much used stability classes (e.g., those due to Klug – Manier [27]) should no longer be employed, as these do not correspond to the present state of the art.

2.4. Air-Pollution Control

Pollutants are always present in the atmosphere, and may be of natural origin (see Section Composition of the Present Atmosphere). The only effective method of reducing additional pollution of human origin is to reduce emissions.

The subject of this section is not the reduction of emissions, but what happens to pollutants after they have been released into the atmosphere, and what can be done to prevent threshold values from being exceeded. The observance of threshold values can be monitored by measuring pollution concentrations. In general, point measurements are taken, so that a result is only applicable to that location. Threshold values are often statistical quantities which must be determined from a number of single measurements. To include all variations of the influential factors (source parameters and meteorological conditions), measurements must be carried out over long periods (one year or more). Only then can it be decided whether threshold values are being exceeded or observed. The measurements provide only a present time and past for each measuring location. To obtain spatial information, and to enable the effects of preventive measures to be forecast (new sources, reduction of emissions, relocation of sources), the extent of the pollution must be calculated.

To obtain statistical information, the concentrations for time series, with the corresponding variations of the input quantities, must be calculated. The calculation is highly time consuming. Frequency distributions of the emissions and the meteorological input quantities are therefore used. The use of several one-dimensional frequency distributions is only possible if the individual parameters are independent of each other. For the most important meteorological input quantities, i.e., wind direction, wind velocity, and stability, this is certainly not the case, so that multidimensional frequency distributions are required.

2.4.1. *Methods of Calculating the Dispersion of Pollution*

There are four methods of calculating pollution concentration:

1. Empirical formulas
2. Gauss formulas
3. Solution of the diffusion equation
4. Particle models

2.4.1.1. *Empirical Formulas*

Empirical formulas give the relationship between measured emissions, immissions, meteorological influences, and geometrical parameters. The simplest formula expresses the fact that the concentration is proportional to the source intensity, is inversely proportional to the wind velocity, and decreases in proportion to a negative index of the distance between the source and the point under consideration. Using this method, cause and effect can be investigated and, within limits, concentration distributions at ground level can be obtained. The method is not transferable, and the formulas must be recalculated if there are changes in the emissions. It is not suitable for forecasting the effects of preventive measures.

2.4.1.2. *Gauss Formulas*

Diffusion experiments using continuous sources at various heights led to the Gauss formula:

$$\bar{C}(x, y, z) = Q/[2\pi\sigma_y(x)\sigma_z(x)\bar{u}] \cdot \exp\left(-\frac{y^2}{2\sigma_y^2(x)}\right) \exp\left(-\frac{z^2}{2\sigma_z^2(x)}\right)$$

where $\bar{C}$ is the concentration (time average), *x*, *y*, *z* are space coordinates (*x* in the wind direction), *Q* is source intensity,

σ_y horizontal spread of concentration perpendicular to the wind direction, σ_z the spread of concentration in the vertical direction, and $\bar{u}$ the mean wind velocity.

Experiments show that the concentration distribution perpendicular to the mean direction of propagation can be represented by Gauss functions [28]. The experiments measure the spreads and show that these depend on the distance from the source, the height, and the stability of the atmosphere.

There are numerous Gauss formulas, all derived from an original formula, which applies to a spreading spontaneous emission that drifts with the wind:

$$C(x,y,z,t) = Q/\left[(2\pi)^{3/2}\sigma_x(t)\sigma_y(t)\sigma_z(t)\right] \cdot \exp\left(-\frac{x^2}{2\sigma_x^2(t)} - \frac{y^2}{2\sigma_y^2(t)} - \frac{z^2}{2\sigma_z^2(t)}\right)$$

t = traveling time of the cloud, $\sigma_{x,y,z}$ = diffusion in the *x*, *y*, *z* directions.

Other formulas can include the effects of influence such as:

1. Height *h* of the source
2. Reflection at the earth's surface, at an inversion, or at a wall
3. Chemical conversions
4. Settling rate of the pollutant
5. Time-dependent emissions
6. Point, line, two-dimensional, and volume sources

Gauss formulas are still extensively used. They are easily understood and simple to use, and the computation is not complicated. However, the conditions under which the Gauss formula can be used are so restrictive (constant meteorological conditions over space and time, flat surface of uniform roughness) that the results calculated can only be used as a guide, and the formula is only suitable for rough calculations. Moreover, better methods are available for calculating concentrations.

2.4.1.3. *Diffusion Equation*

The balance equation for a given substance (diffusion equation) is:

$$\frac{\partial \bar{C}}{\partial t} = -\bar{u}\frac{\partial \bar{C}}{\partial x} - \bar{v}\frac{\partial \bar{C}}{\partial y} - \bar{w}\frac{\partial \bar{C}}{\partial z} + \frac{\partial}{\partial x}\left(K_x\frac{\partial \bar{C}}{\partial x}\right) + \frac{\partial}{\partial y}\left(K_y\frac{\partial \bar{C}}{\partial y}\right) + \frac{\partial}{\partial z}\left(K_z\frac{\partial \bar{C}}{\partial z}\right) + P$$

where time averages are indicated by a bar, K_x, K_y, K_z are exchange coefficients and *P* is the source term.

The change in concentration with time at a point (*x, y, z*) (left-hand side of equation) is determined by:

1. Mass transport to or from the test point by an average wind ($\bar{u}$, $\bar{v}$, $\bar{w}$) at a nonzero concentration gradient (1st to 3rd summand on the right-hand side of the equation).
2. Turbulent transport (4th to 6th summand on the right-hand side of the equation). Mass is transported from the region with an excess to the region with a deficit.
3. Sources and sinks for masses of material.

Analytical solutions to the diffusion equation exist (the Gauss formula is a solution of the diffusion equation given certain preconditions for the relationship between diffusion and distance from the source). However, they cannot be used in practice if meteorological fields vary over space and time, and topographical structures and buildings are to be included. The diffusion equation can then only be solved numerically.

Computation Grid. To obtain a numerical solution of the differential equation, a three-dimensional grid is superimposed on the region in which the concentration calculation is to be carried out. Depending on the mathematical model, the region being studied, and its size, the grid can be rectangular or can follow the topography. The spatial solution depends on the size of the region, the size of the structures to be analyzed, and the speed and storage capacity of the computer. The grid element size lies between 1m and some kilometers. Regions studied can vary from a few meters (e.g., a back yard) to many kilometers (e.g., transport over a large area).

Finite Difference Equation. To obtain a numerical solution, the differential equation must be converted into a difference equation. This gives the following:

$$\frac{\Delta C_{i,j,k,t}}{\Delta t} = \frac{1}{\Delta x}\left\{ u_{i-\frac{1}{2},j,k} C_{i-\frac{1}{2},j,k,t} - u_{i+\frac{1}{2},j,k} C_{i+\frac{1}{2},j,k,t} + K X_{i+\frac{1}{2},j,k} \frac{C_{i+1,j,k,t} - C_{i,j,k,t}}{x_{i+1,j,k} - x_{i,j,k}} - K X_{i-\frac{1}{2},j,k} \frac{C_{i,j,k,t} - C_{i-1,j,k,t}}{x_{i,j,k} - x_{i-1,j,k}} \right\} + \frac{1}{\Delta y}\left\{ v C_{i,j-\frac{1}{2},k,t} - \mathrm{v}_{i,j+\frac{1}{2},k} C_{i,j+\frac{1}{2},k,t} + K Y_{i,j+\frac{1}{2},k} \frac{C_{i,j+1,k,t} - C_{i,j,k,t}}{y_{i,j+1,k} - y_{i,j,k}} - K Y_{i,j-\frac{1}{2},k} \frac{C_{i,j,k,t} - C_{i,j-1,k,t}}{y_{i,j,k} - y_{i,j-1,k}} \right\} + \frac{1}{\Delta z_k}\left\{ w_{i,j,k-\frac{1}{2}} C_{i,j,k-\frac{1}{2},t} - w_{i,j,k+\frac{1}{2}} C_{i,j,k+\frac{1}{2},t} + K Z_{i,j,k+\frac{1}{2}} \frac{C_{i,j,k+1,t} - C_{i,j,k,t}}{z_{i,j,k+1} - z_{i,j,k}} - K Z_{i,j,k-\frac{1}{2}} \frac{C_{i,j,k,t} - C_{i,j,k-1,t}}{z_{i,j,k} - z_{i,j,k-1}} \right\} + \frac{P_{i,j,k,t}}{\Delta x \Delta y \Delta z_k}$$

where i, j, k are the indices of the grid element for the coordinate directions x, y, z and $\Delta C_{i,j,k,t}$ is the concentration change in the grid element with indices i, j, k, in time Δt.

To determine all the summands on the right hand side of the equation, the following are required:

1. The three-dimensional wind field u, v, w
2. The three-dimensional field of the exchange coefficients K_x, K_y, and K_z
3. The three-dimensional concentration field at time $t = 0$
4. The three-dimensional field of the production and dissipation terms $P_{i,j,k,t}$

Also, the boundary conditions and the time interval Δt must be fixed.

The wind field largely determines the concentration field. Over a flat surface of uniform roughness, the wind field is horizontally homogeneous, and only changes with height (see Section Dynamics of the Atmosphere). If the land is topographically organized, the land use diverse, and buildings present, the wind field becomes highly structured and cannot be determined from measurements. A mathematical model must be used to determine the three-dimensional wind field.

Only one equation is necessary to determine the concentration. Wind velocity is a vector, and three components u, v, and w must be calculated to define it (i.e., three differential equations must be solved). Other factors are the pressure-gradient force (which depends on the air pressure), the buoyancy forces determined from the temperature field, and the air density. Hence, the number of variables increases to six, and a coupled system of six equations (4 prognostic and 2 diagnostic) must be solved. The method is used in a number of models. The computation is very sophisticated, and only a limited number of structures can be solved, even using a large computer.

If the extensive information available from wind tunnel experiments and field measurements on wind flows over obstacles is utilized, a wind distribution roughly corresponding to reality can be arrived at. To use this in the propagation calculation, this wind field must simply be made to be free of divergence, which can be realized by the iterative solution of a single differential equation. The calculation time is considerably shorter, and very large regions with many obstacles can be used [29].

Whichever of the two methods is used, a three-dimensional wind field is obtained for the diffusion calculation.

Turbulence Field. The variance in the Gauss formulas corresponds to the exchange coefficients in the diffusion equation, i.e., they represent the dilution of pollutants by the turbulence of the atmosphere. Measurements of the exchange coefficients for the transport of pollutants in the atmosphere are not available. The exchange coefficients cannot be calculated from the variances, as the Gauss formulas used are not solutions of the diffusion equation, and the environmental conditions during the measurements were horizontally homogeneous.

There are theoretical approaches to finding the exchange coefficients for the vertical transport momentum. This method is valid for flat land of uniform roughness, and is established by measurements of the exchange coefficients. It is assumed that the theoretical relationships for any oriented surfaces can be used, and that the exchange coefficients for pollutants can be determined from the exchange coefficients for momentum. The three-dimensional field of exchange coefficients is

then obtained from the wind field and the distance to the solid boundary.

Concentration Field. In general, it is assumed that the concentration field at time $t = 0$ is zero. However, this assumption is not obligatory.

Pollution sources have various spatial structures and behavior patterns with time, depending on their nature. An accident can often be regarded as a point source, and is sometimes an instantaneous emission of material. Emissions from vehicles are linear and vary with time. A sewage treatment plant is a two-dimensional source with an almost constant emission. The spatial structure of the source is fitted to the grid. Thus each discrete source becomes a volume source with at least the size of a grid element. The temporal behavior of the source corresponds to the emissions in the time interval Δt.

Pollution Sinks. Pollutants can disappear by chemical reactions, deposition on the ground, and washout by precipitation; either another substance is formed or the original substance is transferred to the soil or groundwater. The quantity disappearing per unit of volume and time interval is always a certain percentage of the concentration.

Boundary Conditions. Solid boundaries (the earth's surface, walls, and roofs) are impermeable, but material can be deposited there. The side boundaries are permeable, and the upper boundary can be permeable or impermeable (in the case of an inversion). These conditions can be represented by appropriate limits to the flow components and exchange coefficients at the boundaries.

Time Interval. A mathematically stable solution is only obtained if the time interval is sufficiently short. The time interval becomes shorter as the grid element becomes smaller and the wind velocity and exchange coefficient increase. It can vary between 0.5 s and 1 min.

Results. The result of the calculation is the variation with time of the structure of the pollutant cloud. An example is shown in Figure 3, which shows a section at a height of 2.5 m through a calculated pollutant gas cloud 400 s after the onset of emission.

Figure 3. Pollutant cloud from a continuous source, 400 s after start of emission

Horizontal cross section at 2.5 m height, undisturbed flow at 135°

Accuracy. There are a number of sources of error that affect the accuracy of the calculations:

1. Inaccurate emission data
2. Errors in the numerical determination of the wind field
3. Errors in the determination of the exchange coefficients
4. Numerical errors due to the method of computation

As it is not possible to estimate the individual errors, the reliability of the computation must be found by comparing measured with computed figures. Investigations using wind tunnel experiments and field measurements [29] show that the accuracy can be given by the factor 2 or 1/2.

2.4.1.4. *Stationary Solution of the Diffusion Equation*

Continuous sources of constant emission must often be considered. In these cases, only the stationary concentration distribution is of interest. An equation for the determination of this concentration distribution is obtained if the change with time $\partial C/\partial t$ is set at zero in the differential equation. In the stationary case, advective and turbulent flows counterbalance production and dissipation. In this case, too, an analytical solution for normal practical use is not possible, and the differential equation must be converted into a difference equation. The stationary solution is obtained by iteration of the initial field with zero concentration and constant sources and sinks.

Figure 4 shows results for the propagation of car exhaust emissions.

Figure 4. Diffusion of car exhaust emissions

Cross section at height 1.5 m, undisturbed flow at 320°, wind speed at height 10 m 1.7 m/s; traffic only in through streets, 500 vehicles per hour (1000 h^{-1} in upper part of longitudinal street)

2.4.1.5. *Particle Models*

An alternative method for determining concentration fields is by following the paths of a large number of individual particles in a given wind and turbulence field (Lagrange particle model). The use of particle models avoids numerical errors originating from the computing method.

2.4.2. *Use of the Diffusion Calculation*

TA-Luft. For plants requiring a license, a diffusion calculation must be carried out in certain circumstances according to the guidelines of the TA-Luft [30]. A Gauss formula that gives the concentration distribution for a continuous source is used. The concentration at ground level is determined by the intensity of the source, its height (including the effects of the buoyancy of a hot gas if applicable), wind direction, wind speed, and diffusion class. The computation method was developed before 1985, and no longer corresponds to the state of the art. This is especially true for topographically organized land or if land use changes. Some important influences cannot be taken into account, e.g., inversions, chemical changes, and variations in meteorological parameters with location and time. An EC Regulation may possibly supersede TA-Luft.

Safety analysis is compulsory for many plants, especially in the chemical industry [31]. A propagation calculation may be required in the course of such a safety analysis.

Two different questions can arise:

In the case of a flammable gas, a worst-case distance and an average distance from the source at which the gas is still capable of ignition (lower ignition limit) must be stated. With toxic gases, the region in which there is the possibility of a hazard must be established. Here, too, the worst case and the average case are required.

The substances released can be light, density-neutral, or heavy gases, or can be particulate. A gas is assigned to one of these three groups according to its density at the place of release relative to the density of the air. The heavy gases therefore also include cryogenic gases that under normal conditions are not heavier than air and would be grouped with the light gases, and high molecular mass gases at high temperatures are regarded as light.

The spread of *heavy gases* cannot be calculated by the method described above, as in this case propagation is controlled by the force of gravity, and the sudden change in density at the interface with the surrounding air prevents mixing. A heavy gas spreads in a flat layer close to the ground, like a liquid. Obstacles such as fences, walls, houses, and dams can prevent propagation. In streets and on sloping country, channeling takes place, extending propagation.

Analytical or numerical models to determine ignition limits cannot be used, as the effect of obstructions cannot be included. Therefore, VDI guidelines recommend the use of the results of systematic wind tunnel investigations [32]. Dimensional analyses enable the results of small-scale experiments to be transferred to the full scale.

For a continuous source of heavy gas, three characteristic quantities are obtained:

$L_{cc} = (V_0^2/g_e)^{1/5}$ (length scale)
$T_{cc} = (V_0/g_e^3)^{1/5}$ (time scale)
$U_{cc} = (V_0/g_e^2)^{1/5}$ (velocity scale)

where V_0 is the source volume flow in m^3/s in the wind tunnel or in reality, and g_e is the acceleration due to gravity, normalized for the relative density difference.

Wind tunnel experiments show that, in the worst case, the dilution depends only on the normalized distance x/L_{cc}. As the lower limit of flammability is defined by a particular dilution, a constant value is obtained for the normalized distance. If this is multiplied by the characteristic length, which can be determined from the source data, the distance of the lower limit of flammability on the full scale can be found, and it can then be seen whether a safety hazard exists. The VDI guidelines list the results of a large number of experiments with various shapes of obstacles.

In the case of *gases of neutral density*, a modified Gauss model is used in the VDI guidelines [33]. Each emission is divided up into a number of individual clouds emitted sequentially, so that emissions that change with time can also be considered. The worst case is given by:

1. The test point lying on the downwind side of the source
2. A stable temperature stratification
3. A barrier layer at a height of 20 m, or at the height of the upper edge of the highest building

As an average case, the most common wind velocity and diffusion class is used, with no barrier layers.

The variation with time of the concentration at a given test point is calculated. From this, depending on the substance, the relevant parameters, e.g., average value or dose, can be calculated, or the highest value can be found. Point sources, line sources, flat sources, and volume sources can be treated.

Heavy gases are treated like density-neutral gases if the concentration of the heavy gases is < 1 % and the gas can have toxic effects. In this case, the propagation model for heavy gases gives the input values for the diffusion calculation for density-neutral gases.

Light gases have either a relative molecular mass lower than that of the gas mixture air, or the temperature of the gas is significantly higher than that of the surrounding air. Light gases experience a buoyancy. They are accelerated upwards, and the gas only finds its way back to the earth's surface at considerable distances from the source by turbulent diffusion. The maximum concentration is shifted to greater distances. In the guidelines [33], this is accommodated by a displacement of the source in an upwards direction. The height of the source is obtained from the heat emission, and is calculated as

described in the TA-Luft Guidelines [32]. The worst case propagation situation is given by the combination of wind velocity and diffusion class that gives the highest concentration at the test point.

Odor. Factory farming, sewage works, composting plants, waste dumps, and chemical plants can be sources of unpleasant odors. Immissions are directly perceived by people, and can constitute a nuisance. The most important factors determining the degree of the nuisance are frequency, duration, intensity, and nature of the odor, and the opinions of the people affected. Gauss models or solutions of the diffusion equation are not in themselves suitable for calculating odor nuisance, as they give average values for stationary diffusion conditions. The averaging times in the diffusion experiments used to produce the diffusion figures were 30 – 60 min, and the average figures calculated by the Gauss model are therefore also averaged over this time period. In the human nose, the test volume is a few cubic centimeters, and the averaging time is one to a few seconds. Variations in concentration due to atmospheric turbulence lead to large fluctuations in the intensity of the odor.

A VDI guidline [34] enables the frequency of occurrence of the odor of a particular material above a given concentration of the odoriferous substance in the vicinity of single or multiple sources to be determined. This is based on a model that gives average concentrations. It is assumed that these average values are derived from a frequency distribution of concentrations of short averaging time. The frequency distribution can be represented by an exponential function. As well as the probability of detecting an odor, the probability that an odor sensation in excess of the nuisance level will enter the respiratory tract is also obtained.

Accidental Release (⟶ Plant and Process Safety). The main problem with accidental releases of flammable or toxic gases is detecting the accident. Only if an accident is immediately recognized can the appropriate measures be taken to prevent hazards to personnel. The region in which threshold values have been exceeded and the expected duration can be predicted by means of a diffusion calculation. Preconditions for this include:

1. Immediate establishment of the location of the accident and of the temporal behavior of the pollutant source
2. Computational methods significantly more rapid than real time (by a factor of > 10) for calculating the future concentration of the pollutant
3. Criteria for the noxiousness of immission concentrations resulting from the accident

The methods currently used to detect accidental discharges are inadequate, especially where the transport of hazardous goods is involved. In the future, it will be possible to use remote monitoring systems which, when fully developed, will

1. Immediately detect an accident
2. Identify the pollutant
3. Give the spatial distribution of the pollutant concentration
4. Give the changes in the pollutant source with time

Diffusion calculations can already be carried out by personal computers appreciably more rapidly than real time, especially as the accuracy of the diffusion calculation need not be better than the accuracy with which the source term can be determined.

Threshold values for toxic substances are only partially suitable for assessing short-term accidental immissions.

After accidental release a reconstruction of events is often required, or the amount of pollutant material deposited on the ground may have to be determined. An accidental-release calculation can enable the propagation process to be reconstructed, and the emissions can be assessed from the measured immission concentrations. The amount of material deposited and the extent of the region affected can also be determined.

2.4.3. *Environmental Compatibility and Simulation of the Environment*

If the earth is to remain habitable, all human activities must be investigated in terms of whether their consequences are environmentally tolerable. Also, all man-made objects are exposed to the effects of the environment, so that they become contaminated and are eventually destroyed. Consequently, repair, replacement, and even disposal may be necessary, so causing further pollution of the environment.

Attempts can be made to solve the first problem by means of environmental compatibility studies, experiments, and tests [35]. For this, all the effects on the soil, water, and the atmosphere must be taken into account. The effects on the atmosphere can be divided into effects on air quality and effects on the climate.

Environmental simulations aim to provide information on the durability of manufactured objects. Here, too, the effects of air pollution and climatic influences are investigated [36].

Environmental Compatibility. The question of the effects of air pollutants is closely linked with the diffusion calculation. For given emissions, immission concentrations and amounts of material deposited or absorbed can be found. From this, the effects on humans, animals, plants, monuments, and natural features can be derived. Synergistic effects can never be excluded, but assessment of these is difficult. Climatic effects (air temperature, air humidity, rain, sunlight, and wind) on the human population are difficult to quantify. Normally, humans, animals, and plants have a wide tolerance range within which they can live without harm. The lack of specific receptors for the individual components of the climate and the variable susceptibility of people (e.g. due to age and state of health) means that different effects can produce the same stress.

Combinations of meteorological parameters can be regarded as separate entities, and subjective descriptive terms can be applied to them, such as harmful, stress-inducing, causing nuisance, neutral, beneficial, or useful.

The effects of corrective measures on, e.g., air temperature and humidity, ventilation by the wind, and sunlight can be predicted by mathematical models. The combined effects of climate and pollution are sometimes very important, but it is not at present possible to quantify these.

Environmental Simulation. Simulation of the environment aims to predict the functionality and lifetime of products. In environmental simulation experiments, the essential characteristics of the environment must be modeled, and a time-compression technique is necessary. Synergistic effects must be included.

In laboratory experiments, only one parameter is usually investigated, and the time compression can be achieved by increasing the dose. Limits are imposed by the necessity for a linear dose – effect relationship. In field experiments, the magnitude of the causal influences are often not known, and only the effects can be analyzed. Also, forecasts of future events must be made from minimal changes and short exposure times. Numerical environmental simulation is only in the early stages of development. The degree of time compression depends on solely computer capacity. However, there is in particular a lack of essential information about processes occurring at the atmosphere – object interface.

3. Effects of Air Pollutants

Thomas Eikmann and Gerhard Scholl

3.1. Effects on Humans

Air pollution has always been an undesirable byproduct of human activities, and has presumably had harmful effects on human health ever since the cave dwellers lit their first fire. The problem increased with the growth of human settlements, the practice of crafts and trades, and the extensive development of large industrial concentrations starting in the mid-1800s. Smog episodes, e.g., in 1930 in the Maas Valley (Belgium), in 1948 in Donora, Pennsylvania, and in 1952 in London attracted the attention of a wide section of the public to the problems of health damage by air pollutants and the consequent increase in the death rate of especially vulnerable sections of the community.

Continuing structural change in post-industrial society, including a decrease in classical industrial operations (e.g., the coal and steel industries) and a simultaneous increase in the importance of the service industries, has led to considerable changes in the release of emissions, with consequent reductions in the extent to which the population is exposed to air pollutants.

Land can no longer be divided up into highly polluted industrial regions and so-called clean air regions according to the amount of pollution, mainly because of the increasing impact of traffic and the reduction in the release of harmful substances from stationary emitters (e.g., power stations, domestic heating, and coking plants). Today, areas of a high traffic density in rural regions can sometimes have higher immission concentrations of pollutants than areas of low traffic density in large cities.

The increasing importance of hitherto unknown emissions has led to increasing effects of these other pollutants on the health of the population. As well as the substances typical of motor vehicles (mainly benzene, nitrogen dioxide, and ozone), persistent chlorinated organic compounds play an ever-increasing role in the exposure of the human population to pollution (including secondary accumulation in foodstuffs).

Furthermore, there has been a significant increase in indoor air pollution. Changes in living conditions (longer periods spent in enclosed spaces), the use of new types of construction materials, and changes in behavior patterns (e.g., inadequate ventilation) have increasingly led to health damage (sick building syndrome).

As a result of this, and also of the general population's continuously increasing awareness of the environment, a tendency towards individual risk assessment has become noticeable. The statistical observation of health hazards is carried out by (epidemiological) methods different from those used to investigate individual risks, so that it has been necessary to develop new techniques of observation and investigation. Examples of this are the provision of out-patient departments specializing in environmental medicine for the clinical examination of patients and the rapid development of environmental medicine as a branch of general medicine.

3.2. General Effects

The effects of air pollutants on humans can range from simple nuisance (e.g., an odor) to serious health damage (e.g., periods of smog in London in 1952 caused over 4000 deaths). A large number of substances cause air pollution, and their concentration in the air varies greatly with time and location, depending on weather conditions (transmission effect) and the various types of emitters involved. Today, their concentrations are in general very low (e.g., compared with those at the workplace), so that an assessment of health damage can only be carried out by considering combination effects in the low ose range. Competing effects from the private actions of individuals (e.g., smoking, medication) and exposure by other routes (e.g., water and food) must also be considered. Especially when long-term (chronic) effects are being investigated, epidemiological studies on representative population groups are carried out, (e.g., investigations of health effects in the “clean air” zone of North Rhine-Wesphalia, Germany).

The respiratory tract, with its large inner surface area, is the main site of damage by air pollutants. However, there can also be effects on the heart and circulatory system, blood formation, the kidneys, the immune and nervous systems, and the skin. Air pollutants relevant to environmental medicine include sulfur dioxide, nitrogen dioxide, ozone, carbon monoxide, dusts, heavy metals, and a wide range of hydrocarbons and chlorinated hydrocarbons. Of special significance are air pollutants that are regarded as potential carcinogens. Important substances of this type include arsenic, benzene, cadmium, diesel motor emissions (DME), polycyclic aromatic hydrocarbons (PAH), and 2,3,7,8-TCDD (dioxin).

3.2.1. *Specific Pollutants*

It is considered that an effect on humans by an environmental pollutant has been caused if reversible or irreversible changes to normal physiological processes are caused in the human organism. The scheme of continuous biochemical activities is changed by the substance in question, and this can be detected and observed. In the case of substances with a reversible effect, it is possible to specify a dose or exposure concentration below which no effect is produced or can be observed. The presence of the substance at concentrations below this threshold can therefore be regarded as harmless to health.

In the case of substances that have an irreversible, carcinogenic, mutagenic, or allergenic effect, it is assumed that an effect threshold does not exist. Since a risk is present even at low concentrations, special efforts must be made to reduce or limit such pollutants.

The specific characteristic effects of a substance are mainly a function of a combination of dose, exposure time, the nature of the effects, and the fundamental mechanism of these effects. In the context of environmental pollutants, “effect” means any change which is brought about by a substance after acute or chronic exposure. Damage to health means reversible or irreversible undesired changes caused by a substance or factor. Toxicity is the ability of a substance or factor to cause such damage, depending on the applied dose and exposure time. Risk is defined as the probability that a given damage occurs in that part of a population exposed to a harmful agent.

The effects of environmental pollutants are assessed by using the results of animal experiments, in vitro experiments on biological material, human case studies, and epidemiological investigations. The derivation of standard values for the protection of human health is mainly based on case studies of humans.

The toxicological basis for such values is the lowest concentration which leads to detectable harmful effects on humans and/or animals (LOAEL = lowest observed adverse effect level) and/or the highest dose at which no known adverse effects have so far been detected in humans or animals (NOAEL = no observed adverse effect level). In accordance with the WHO definition, the LOAEL is the lowest concentration of a substance at which definite detrimental changes to morphology, functionality, growth, development, and life expectancy of the organism concerned is to be expected.

When standard values are derived from the LOAEL, safety and protection factors must be used, including the following:

1. A safety margin in the estimation of a no effect level
2. Interindividual differences (toxicokinetic and toxicodynamic differences)
3. Interspecies differences (toxicokinetic and toxicodynamic differences)
4. The simultaneous effect of several substances, or their combined effects
5. Variation in the sensitivity of persons (special risk groups)
6. Severity of the effects
7. Exposure by other routes (e.g., food contamination)

3.2.2. *Persons Needing Special Protection*

Because of their general sensitivity to the pollutants, children, pregnant women, old and ill persons, and persons with a genetic predisposition must receive special consideration when assessing the effects of (air) pollutants. For example, persons with chronic bronchitis or bronchial hypersensitivity are especially susceptible to substances which attack the respiratory tract or lungs. This is exacerbated in children, because they have higher volume per minute respiration rates per unit body weight than adults, and are more sensitive to infections.

Persons sensitive to (air) pollutants also include allergic persons for whom the frequency and severity of allergic reactions can be intensified by certain nonallergenic foreign substances in the air. Thus, the percentage of children with hay fever is significantly higher in areas of high traffic density than in traffic-free areas, even though the pollutants themselves do not have an allergenic effect [37].

Setting guideline values for the protection of especially sensitive persons (e.g., those with congenital immune deficiency or other special idiosyncrasies) is difficult. Thus it is not possible to specify a dose of an allergen that will have no effect on an allergic person. For these persons, the standard values for pollutants derived for a normal population cannot guarantee freedom from complaints. Here, further measures should be taken in addition to those recommended in the standard regulations.

3.2.3. *Carcinogenicity, Mutagenicity, and Teratogenicity*

Carcinogenicity is the ability of a substance or physical factor to cause cancer in humans or animals (⟶ Carcinogenic Agents). Cancer-risk factors can lead to the uncontrolled and unorganized formation of neoplasms, which include both benign and malignant tumors. Carcinogenic factors can include ionizing and UV radiation, numerous chemical substances, and oncogenic viruses. Also, immune deficiencies, hormonal influences, and inherited predispositions affect the formation of cancer.

The development of malignant tumors takes place in three phases, according to the multi-stage model:

1. Initiation: in general, the sudden appearance of a persistent cell modification that is transmitted to the descendants of the cell. It gives the affected cell the ability to form a tumor when acted upon by a promoter.
2. Promotion: a lengthy process (weeks to years) in which the action of promoters (cancer-risk factors) cause cells modified by initiation to multiply. Promoters by themselves are not sufficient for the production of malignant cells, but increase the risk of progression to a malignant tumor.
3. Progression: increase in autonomy and malignity (manifestation of a tumor).

Processes that intensify the initiating action of a substance are known as cocarcinogenic processes. Syncarcinogenicity

means the cooperation of several carcinogenic substances, leading to the additive or superadditive intensification of the action of the individual substances. Anticarcinogenic processes are those in which cancer formation is inhibited or prevented by the effects of chemical factors.

Humans are exposed to a large number of carcinogenic substances via various environmental media (e.g., water, soil, air, food), and physical and biological factors can also play an important role. The risk of cancer can be obscured by general environmental factors, individual behavior patterns (e.g., smoking, diet, and hobbies), and/or by stress at the workplace. Risk estimates in the United States indicate that the effect of environmental factors in the narrower sense (exposure to pollutants in water, soil, and air) on the overall death rate due to cancer is quite small (ca. 5 %).

Causative factors in cancer death rates in the United States [38], [39], given as percentages of all cancer deaths, are as follows:

General anthropogenic pollution (e.g., indoor air, air, drinking water, soil, abandoned polluted areas, pesticides)	2 %
Geophysical factors (e.g., exposure to sunlight, pollution of indoor air by radon, general radiation)	3 %
Workplace	4 %
Industrial products	<1 %
Tobacco consumption	30 %
Alcohol	3 %
Food	35 %
Food additives	<1 %
Reproductive and sexual behavior	7 %
Medication and medical procedures	1 %
Infections	10 ?
Unknown	?

Although there is clearly a risk of cancer even when the above-mentioned effects are excluded any additional burden from the environment should be minimized. An additional cancer risk of 5 % would mean an additional 22 000 cancer deaths per year in the United States.

The carcinogenicity of a substance is usually expressed as the unit risk (risk coefficient), which indicates the risk of cancer from lifelong exposure, e.g., to 1 µg of a carcinogenic air pollutant per cubic meter of respired air. Generally, the “upper-bound risk value” is given; i.e., there is a probability of 95 % that the actual risk is less than the unit risk. The virtually safe dose (VSD) is the daily dose based on a lifetime's exposure (70 years) that leads to an acceptable theoretical additional risk over and above the background risk.

Mutagenicity is the ability of a substance or physical agent to cause permanent structural changes in the genetic information of cells in vivo and in vitro (⟶ Mutagenic Agents). The changes can involve one or more genes, one or more chromosomes, or sections of chromosomes. Mutations in gametes are transmitted to their descendants. Mutations in body cells remain in the organism in which they were induced.

Teratogenicity is the ability of certain chemical substances, microorganisms, or ionizing radiation to cause nontransmissible malformations, mainly in mammalian embryos (⟶ Teratogenic Agents). According to German chemical legislation on hazard data for substances and preparations, a substance with teratogenic effects has the ability to harm prenatal human life, causing irreversible disturbance to fetal development in the mother's body or irreversible impairment of the post-natal development of the child. In theory, all substances can have a harmful effect in all phases of reproduction. Reproductive toxicology deals with the effects of compounds on the sperm and ova, on conception and implantation, on organ formation, and on fetal maturity. It is not yet known precisely how the formation of defects in embryos occurs. It is thought that teratogenic effects arise through gene damage due to chromosome aberrations, disturbances to mitosis, or inhibited or faulty synthesis of nucleic acids.

3.3. Environmentally Relevant Air Pollutants

3.3.1. *Sulfur Dioxide*

Sulfur dioxide (SO_2) is an irritating gas which can be retained to 90 % in the nasal passages on inhalation owing to its high solubility in water. It can reach the lower respiratory passages if its concentration is very high, if it is adsorbed on dust particles, or if breathing is mainly through the mouth. Dust particles can then catalyze the production of sulfur trioxide (SO_3). SO_2 is absorbed from the respiratory tract into the blood. After biological conversion to sulfate, it is mainly excreted in the urine. Only a few minutes after exposure, the distribution of sulfates by the blood into the tissues and organs and their excretion in the urine can be detected. Radioactively labelled sulfur compounds can be found in the lungs up to one week after exposure.

No systemic toxicity or damage to organs due to SO_2, including mutagenic or carcinogenic effects, have so far been observed. The effects of sulfur dioxide and of the acids formed from it vary in severity, depending on the state of health of the exposed person. Persons already suffering from lung and bronchial diseases must be regarded as high-risk groups. Furthermore, short- and long-term exposure, and the effects of physical stress under certain conditions of exposure require special assessment.

Numerous studies have shown that changes in lung function only occur in healthy subjects at very high SO_2 concentrations, untypical of the environment. However, in the case of respiratory systems already affected by chronically obstructive diseases and asthma, sensitivity to SO_2 can be many times higher. SO_2 concentrations of > 10 000 µg/m^3 can lead to restriction of ciliary motion and slowing or cessation of mucociliary transport, with consequent impairment of lung clearance. Acute effects are bronchoconstriction, bronchitis, and tracheitis. Physical exertion, with increased respiration rate and volume, can significantly lower the threshold concentration of 10 000 µg SO_2/m^3 [40], [41].

Young asthma sufferers exposed to SO_2 by inhalation through a mouthpiece, with simultaneous physical exertion, show noticeable effects on lung function at the low concentration of 100 µg/m^3. However, with asthmatic adults, a concentration of at least 350 µg SO_2/m^3 is necessary. Simultaneous exposure to 300 µg SO_2/m^3, 100 µg NO_2/m^3, and 50 µg ozone/m^3, leads to an increase in bronchial sensitivity in the provocation test with histamine, carbachol, acetylcholine, etc. [42].

In chronic exposure to SO_2, the main effect is an increased incidence of bronchitis and other symptoms of infection. Furthermore, investigations of the effects of exposure to SO_2 at typical environmental concentrations using spirometric tests showed that lung function was affected. An investigation of 200 schoolchildren in an industrial area showed that exposure to increasing SO_2 levels (up to 281 µg SO_2/m^3) and particle concentrations led to impairment of the enforced vital capacity and the 1 s capacity. Also, ca. 25 % of the children studied showed a ca. four-fold sensitivity to pollution [43].

Reduction of the enforced lung function was observed in adult patients with chronic obstructive respiratory ailments on a 5-d exposure to 190 µg SO_2/m^3 (peak figure 720 µg SO_2/m^3) and 44 µg dust particles/m^3. Also there was a significant increase in the observable effects at low air temperatures (< 0 °C). Impairment of lung function (oscillatory resistance) in normal population samples was observed on increasing the 24-h mean value of 60 µg SO_2/m^3 to 256 µg SO_2/m^3 with simultaneous exposure to airborne particles in concentrations of 69 µg/m^3 and 179 µg/m^3 respectively (24-h mean values) [44].

In Japan, using normal population samples, an increase in the incidence of bronchitis in men from 5.5 % to 6.7 % was observed, and in women from 1.1 % to 3.9 % when the sulfur dioxide level increased from 60 µg SO_2/m^3 to 140 µg SO_2 /m^3. The corresponding concentrations of airborne particles were 100 µg/m^3 and 200 µg/m^3, respectively. The smoking behavior of the sample groups investigated were standardized. Investigations on the normal population in Germany showed that when the sulfur dioxide level increased by ca. 50 µg/m^3, a 10 % increase in the incidence of bronchitis occurred [45].

In children, an increase in the long-term chronic exposure to 181 – 275 µg SO_2/m^3 and 230 – 310 µg airborne dust/m^3 led to increased incidence of diseases of the lower respiratory tract compared with children from a control region with lower air pollution. Also, in other studies of children from variously polluted regions, a correlation between the frequency of diseases of the lower respiratory tract and the degree of pollution was found [46].

A series of epidemiological investigations into the effect of SO_2 on health were carried out on chronically exposed population groups in polluted areas during smog episodes in which the concentrations of pollutants (mainly SO_2 and dust) were extremely high for brief periods. Here, it was shown that exposure over several days led to an increase in the death rate of older people with chronic obstructive lung diseases or heart diseases when the mean 24-h concentration of SO_2 reached ca. 700 µg/m^3 and the airborne dust concentrations simultaneously rose to 500 µg/m^3 [46].

During the smog periods in North Rhine-Westphalia in January 1985, a significant increase (8 %) in the death rate occurred in the polluted area. Hospital admissions for respiratory and cardiovascular diseases increased by 17 %, and a marked correlation with age was noticeable, the increase being greater in older people. The highest 24-h mean values in the polluted area were 830 µg SO_2/m^3, and, in a control area, 320 µg SO_2/m^3. The corresponding airborne dust concentrations were 600 µg/m^3 and 190 µg/m^3 [47].

When setting threshold values for SO_2 in the air, it should be noted that in many cases SO_2 immission values were used as indicators of air quality when classifying effects from epidemiological investigations, whereas other pollutants that were also present as immissions in high concentrations were disregarded. However, especially in humans, a combination effect with particulate air pollutants present at the same time must be assumed.

In Germany, the TA-Luft Regulations for sulfur dioxide specify an arithmetic annual mean value of 140 µg/m^3 (IW 1) and a 98 % value of 400 µg/m^3 “for protection against health hazards”. The maximum immission concentrations (MIK values) specified by the VDI Air Pollution Commission are 1000 µg/m^3 for the 30-min value and 300 µg/m^3 for the 24-h mean value. The World Health Organization (WHO) has recommended the following guidelines: 500 µg/m^3 as the 10-min maximum and 250 µg/m^3 as the 1-h maximum. When SO_2 is present with airborne dust (black smoke), the specified 24-h mean value is 125 µg/m^3 for both SO_2 and airborne dust, and the 1-a mean value is 50 µg/m^3 [48-50].

3.3.2. *Nitrogen Oxides*

The nitrogen oxides NO and NO_2 are important air pollutants. Health hazards are almost exclusively associated with NO_2

and its reaction products, while NO acts as a reservoir from which nitrogen dioxide is produced.

Nitrogen dioxide is a strongly irritant gas. On inhalation, the mucous membranes of the respiratory tract are attacked, the gas reacting immediately with the moisture present there and on alveolar surfaces. It probably does not reach the lung capillaries, although lung function is affected. On inhalation, 80 – 90 % of NO_2 is absorbed in the respiratory tract. Absorption possibly occurs by formation of nitrous and nitric acids or their salts, as indicated by the detection of nitrite and nitrate in the urine and blood after NO_2 inhalation.

The odor threshold lies in the range 200 – 440 µg/m^3. Under controlled conditions, effects on the lung function of healthy experimental subjects are detectable above a concentration of 3800 µg NO_2/m^3. In the case of asthma sufferers under physical exertion, effects on lung function occur above 560 µg/m^3. The combined effects of NO_2, SO_2, and ozone at low concentrations increase the sensitivity of the respiratory tract to acetylcholine [40].

In the case of bronchitic patients, a fairly rapid increase in the respiratory tract resistance takes place in the concentration range 3000 –3760 µg NO_2/m^3. Moreover, at higher concentrations, a decrease in the alveolar – arterial oxygen pressure difference, increased sensitivity to acetylcholine, and an increase in the respiratory tract resistance caused by carbachol is observed. The results of epidemiological studies on the relationship between NO_2 exposure and health effects should not be used for determining threshold limit values for the protection of personnel because other pollutants are also usually present [51].

The effects observed in animal experiments are of only limited applicability to humans, as combination effects with other pollutants are generally not considered. Short-term and single exposures of rats in the low concentration range (380 µg NO_2/m^3) led to inhibition of prostaglandin metabolism. At concentrations of ten times this figure, metabolic impairment was of the same order of magnitude, although the recovery time was significantly extended (<70 h). The observed decrease in prostaglandin breakdown can lead to changes in the respiratory tract and disturbance of the blood flow through the lungs [52].

Long-term exposure of experimental animals at 190 – 1900 µg NO_2/m^3 led to thickening of the alveolar capillary membrane, loss of the ciliary epithelium, and collagen formation in untypical areas of the lungs. In rats, the inhalation of 900 µg NO_2/m^3 for 4 h led to the degranulation of fat cells, followed by excretion of histamine [53].

In a series of studies, increased sensitivity towards viral and bacterial infections after chronic exposure to NO_2 has been demonstrated. Prolonged inhalation of 940 µg NO_2/m^3 by mice leads to increased sensitivity towards *Klebsiella pneumoniae*, the magnitude of this effect appearing to depend more on the concentration than on the total dose. On the basis of the results of animal experiments, it can be assumed that humans will also experience weakening of the immune system on exposure to NO_2 or combinations thereof with other air pollutants.

In Germany, the TA-Luft Regulations specify the following levels of nitrogen dioxide “for protection against health hazards”: 80 µg/m^3 as the annual arithmetic mean (IW 1) and 200 µg/m^3 (IW 2) as the 98 % value. The maximum immission concentrations (MIK values) laid down by the VDI commission on air pollution are 200 µg/m^3 as the 30-min mean value and 100 µg/m^3 as the 24-h mean value. The following guidelines are recommended by the World Health Organization (WHO): 400 µg/m^3 as the 1-h mean value and 150 µg/m^3 as the 24-h mean value [48], [50], [54] (see also Chap. Laws and Technical Regulations).

3.3.3. *Ozone*

Ozone (O_3) is a highly reactive gas that can change or decompose enzymes, coenzymes, and proteins by oxidizing thiol groups, and can oxidize fatty acids to toxic fatty acid peroxides. Protein and lipid membranes are the main sites of attack by ozone.

Ozone is mainly absorbed via the respiratory system, where rapid reaction with the tissues occurs. In many animals, acute exposure to high concentrations of the gas (440 – 1000 µg/m^3) causes rapid, shallow breathing, increased resistance of the respiratory system, reduced vital capacity, and bronchial hyperreactivity. Younger animals show higher sensitivity to these concentrations of ozone. An 8 °C increase in the air temperature doubles the toxic effects. Investigations have shown that concentration is more significant than exposure time.

Numerous animal experiments have demonstrated that chronic exposure to concentrations between 200 and 1000 µg O_3/m^3 has a number of harmful effects, including inflammation of the bronchiole region leading to lung emphysema with fibrosis; reduction of the inhalation and exhalation capacity per second; and decreased lung compliance (elasticity). Inhalation capacity per second is the most sensitive indicator of lung function, and a significant and detectable reduction is apparent at 240 µg O_3/m^3. When rats were exposed for 93 d to as little as 120 µg O_3/m^3, an increase in the ketosteroids in the urine and a decrease in the cholinesterase activity occurred. At 200 µg O_3/m^3, biochemical changes in the lung tissue take place, and above 1000 µg/m^3, a decrease in the surfactant concentration can be detected [40], [55], [56].

Both short- and long-term exposure to ozone cause increased mortality rates in animal experiments (60 – 160 µg/m^3). This has been attributed to decreased antibacterial activity of the lung tissue [55], [56].

The odor threshold of ozone for humans is 20 – 40 µg/m^3. Lower concentrations lead to odor acclimatization. Subjective effects such as lachrymation (caused by other substances present with the ozone), irritation of the respiratory system, coughing, headache, and respiratory discomfort are observed above a concentration of ca. 200 µg/m^3. In school children and adults, changes in the lung function parameters (e.g., reduction of enforced exhaled air volume and increase in the resistance of the respiratory system) appear at concentrations between 160 and 300 µg/m^3. In clinical exposure experiments with volunteer subjects, detectable changes to lung function parameters were detected after 6.6-h exposure to 160 µg O_3/m^3 or 1 – 3 h exposure to 240 µg/m^3 combined with physical exertion [55], [56].

Deterioration in physical fitness was observed at 240 – 740 µg O_3/m^3. With maximum physical exertion (competitive sport), a decrease in performance was detected at considerably lower ozone concentrations. Inflammatory reactions of the tissues of the respiratory tract appear above 160 µg/m^3 after 6.6-h exposure with intermittent physical activity. Also, an increase in the incidence of asthma attacks was noted at 240 – 300 µg/m^3 [55], [56].

At ozone concentrations of >1000 µg/m^3, marked changes to lung function occur, with a significant reduction in the diffusion capacity and one-second capacity. The effects of ozone on lung function show considerable individual differences. Approximately 20 – 30 % of the population show pronounced reactions. Also, there is an increase in the number of cells of the immune system, the fragility of the erythrocytes increases, and visual impairment occurs (e.g., reduction in visual acuity and changes in the field of vision).

In general, children show similar changes in lung function to those exhibited by adults after exposure to ozone. Older persons generally react less often than young adults, but their symptoms are often more severe. In epidemiological investigations, a correlation between typical environmental concentrations of ozone and temporary changes to lung function are reported. When respiratory diseases are already present, a deterioration in health can occur. Investigations on children show a connection between levels of the daily maxima of the ozone immission concentrations and impairment of lung function. Such changes were observed above 120 µg/m^3. This exposure concentration is significantly below those used in experimental investigations. The difference is probably due to the simultaneous presence of other pollutants. Symptoms such as irritation of the eyes, nose, and throat; chest pain, coughing; tiredness; and nausea were observed in children subjected to ozone concentrations of >200 µg/m^3. In asthmatic patients, as the severity of the disease increased, a correlation between the frequency of attacks and the ozone concentration was observed. People with obstructive lung diseases and smokers generally do not react to ozone more sensitively than healthy subjects. However, patients with limited lung function show more severe reactions compared to persons not so affected [56].

Carcinogenic effects of ozone have not so far been proved. However, ozone can have effects resembling those caused by radioactivity, and even low ozone concentrations (200 µg/m^3) in cell cultures can cause chromosome rupture resembling the effects of X-rays. Therefore, although there is no indication of increased cancer rates in occupational groups exposed to ozone, a carcinogenic effect of ozone cannot definitely be excluded.

High-risk population groups include all persons frequently exposed to prolonged strenuous physical activity in the open air on hot summer days. These are mainly healthy children and adults who take part in games or sport, and persons involved in strenuous work in the open air.

In Germany, the VDI Air Pollution Commission has set a 30-min mean value of maximum immission concentrations (MIK value) of 120 µg/m^3. Exposures of up to 400 µg/m^3 for a period of up to 30 min should not occur more frequently than once per week. The environmental ministers' conference has specified a maximum figure of 180 µg/m^3. If this is exceeded, a recommendation should be made to the public along these lines: “Persons who have found from experience that they are especially sensitive to ozone (or other pollutants) should not take prolonged strenuous exercise in the open during the afternoon.” The WHO recommends a 1-h figure for ozone of 150 – 200 µg/m^3. To prevent chronic damage to health, an 8-h figure of 100 – 200 µg/m^3 is recommended.

3.3.4. *Carbon Monoxide*

Carbon monoxide (CO) is a colorless, odorless, and tasteless gas, with low solubility in water. It is formed by the incomplete combustion of carbon or carbon-containing compounds.

Carbon monoxide affects humans by combining with hemoglobin (Hb) to form carboxyhemoglobin (COHb). Carbon monoxide blocks the divalent iron center of Hb by displacing oxygen without change of oxidation state. Carbon monoxide forms a bond with hemoglobin that is ca. 240 times as strong as that formed by oxygen. Therefore, even at comparatively very low concentrations it blocks the oxygen-binding site, and prevents oxygen transport by the blood. The bond between CO and hemoglobin is reversible, and when an intact organism breathes CO-free air, all the CO is eventually released and replaced by O_2, and Hb functionality is fully restored. If pure oxygen is breathed, the regeneration process is much faster. As CO is formed endogenously in normal metabolism, unexposed persons have 0.8 % COHb in their blood. On average, smokers have ca. 7 % COHb, and this rises to 15 % COHb for heavy smokers [40].

All the symptoms of carbon monoxide intoxication are due to oxygen deficiency in the tissues and the accumulation of carbon dioxide during normal metabolism. Unlike reduced hemoglobin, COHb cannot carry away the carbon dioxide. The most important effects are on the central nervous system and the cardiovascular system. The symptoms of carbon monoxide intoxication depend primarily on the COHb concentration in the blood, which is in turn affected by a number of factors including the CO concentration in the respired air, the respiration-time-volume, the duration of the exposure, the oxygen demand of the tissues, and the Hb concentration.

The symptoms of carbon monoxide intoxication with increasing COHb content of the blood [58] are as follows:

5 – 10 %	Slight, measurable visual impairment (threshold of fusion frequency)
10 – 20 %	Slight headache, lassitude, malaise, shortness of breath with exertion, palpitations
20 – 30 %	Vertigo, partial loss of consciousness, limpness and paralysis of limbs
30 – 40 %	Pink skin color, loss of consciousness, shallow breathing, circulatory collapse
40 – 60 %	Deep unconsciousness, paralysis, Cheyne-Stokes respiration, decrease in body temperature
60 – 70 %	Death within 10 min to 1 h
>70 %	Death within a few minutes

Within limits, the healthy organism can compensate for oxygen deficiency caused by CO, in the long term by an increase in hemoglobin, and in the short term by increasing the flow of blood through the organs at risk. Neurophysiological investigations and experimental behavior studies show a significant decrease in the ability to concentrate in healthy persons with 2.5 % COHb. This effect can be important in regions of high exposure concentrations (e.g., traffic jams in road tunnels).

In persons with cardiovascular diseases (heart muscle diseases) and sclerotic changes in the blood vessels of the heart and brain, harmful effects appear at relatively low concentrations (2.8 – 3 %). For instance, in 1000 metallurgical workers exposed to CO for at least 4.2 years, a linear correlation between CO dose and angina pectoris symptoms was established. These industrial medical findings were supported by results of experimental investigations. For example, angina pectoris patients, after a 90-min journey in an open vehicle through Los Angeles, showed a significant reduction in the time required for the appearance of typical chest pain compared with the time required after a journey in which synthetic air was inhaled. The COHb level in the patients after the journey in the open vehicle was 5.08 %, and 0.65 % after breathing synthetic air [58], [59].

According to calculations, a 24-h exposure to air containing 10 mg/m^3 CO produces a maximum of 1.5 % COHb, a 30-min exposure to 30 mg/m^3 CO produces 2.3 % COHb, and a 30-min exposure to 50 mg/m^3 CO gives a maximum of 2.8 % COHb [58], [60].

In Germany, the TA-Luft Regulations for carbon monoxide “for protection against health hazards” specify an arithmetical annual mean of 10 mg/m^3 (IW 1), and 98 % figure of 30 mg/m^3 (IW 2). The maximum immission concentrations (MIK values) specified by the VDI commission for air pollution are 50 mg/m^3 for the 30-min figure and 10 mg/m^3 for both the 24-h and annual mean figures. The WHO recommends the following figures: 15 min: 100 mg/m^3, 30 min: 60 mg/m^3, 1 h: 30 mg/m^3, and 8 h: 10 mg/m^3 [48], [50], [61].

3.3.5. *Dusts*

Dusts are defined as dispersions of solid materials in gases. The particles can be of any shape, structure, and density, and can be up to ca. 100 µm in size. They are formed either by entrainment or mechanical processes. Like smoke and fog, dusts are types of aerosol.

The health hazard due to dusts depends on chemical composition, concentration, exposure time, and especially particle size. This last parameter distinguishes dusts from gases and vapors. Dusts are principally absorbed by respiration. The transport and deposition of a dust in the respiratory tract are mainly determined by the behavior of particles in flowing gases. The characteristic parameter is the aerodynamic diameter d_{ae} of a particle. The aerodynamic diameter of a particle of a given shape and density is given by the diameter of a sphere of unit density (1 g/cm^3) which has the same sedimentation rate as that of the particle in still air or air moving with laminar flow. Fine particles of size <10 µm are regarded as airborne dust [62].

Dust fractions are classified according to their particle size as follows: coarse dust: diameter >50 µm, medium-size dust: 10 – 50 µm, fine dust: 0.5 – 10 µm, and very fine dust: <0.5 µm. So-called respirable dust (airborne dust), which consists of particles of size <10 µm, is of relevance to health.

Particulate pollution (dust) is a mixture of many chemical substances that can have a wide range of effects both separately and in combination. They can be of natural or anthropogenic origin. The main constituents of atmospheric dust are sulfates, carbonates, nitrates, halides, silicates, salts and oxides of calcium, iron, potassium, sodium, aluminum, magnesium, and organic substances. The components with toxic potential include heavy metals, arsenic, polycyclic aromatic hydrocarbons (PAH), and chlorinated hydrocarbons.

Depending on their chemical and physical properties and the duration of their effect, dusts can cause morphological damage and changes to the function of the lungs or to their susceptibility to infection. The particular part of the respiratory tract affected by dusts depends mainly on their particle size. Particles of >10 µm diameter only reach the nose and throat area, and do not enter the middle to lower regions. They can also be carried into the digestive tract by the lung clearance mechanism. The tracheobronchial dust is the dust fraction deposited in the area of the mucociliary clearance apparatus of the tracheobronchial system, and this too can be carried into the digestive tract. Alveolar dust is the dust fraction deposited in the alveolae and in the region of the bronchioles without mucociliary clearance. Via the tracheobronchial system, it can appear both in the digestive tract and in the interstitial tissue of the lungs.

The effectiveness of dust transport mainly depends on the presence of an intact bronchial mucous membrane. The

transport rate can be adversely affected by medication or toxic substances. Effects of gaseous substances such as SO_2 and NO_2 on ciliary activity and mucociliary clearance have also been observed.

Dusts can contribute to the acute effects of smog and can also cause chronic effects. Acute dust pollution always gives rise to health effects that can be unambiguously detected in experimental and epidemiological investigations. The most important first acute effects of dust are impairment of the clearance mechanism of the respiratory system and irritation of the bronchial mucous membrane. The lowest dust concentrations, derived from periods of smog in London and New York, at which an effect on death rate due to disturbances of respiratory function can be detected are in the region of 0.15 mg/m^3. The first changes to the lung function of children were detected at an airborne dust concentration of 0.18 mg/m^3 in the middle of the day [40], [63].

Longer exposure leads to cytotoxic effects and tissue damage. The first effects are observed at an annual average concentration of airborne dust of > 0.09 – 0.15 mg/m^3. More recent industrial medical investigations have shown that dust at the workplace can promote chronic bronchitis, although cigarette smoke has a significantly greater influence. At today's low dust concentrations in the outside atmosphere and also indoors, it may prove very difficult to detect long-term effects on the incidence of chronic bronchitis by epidemiological methods against the background of active and passive smoking.

In Germany, the TA-Luft Regulations for airborne dust (irrespective of its constituents) specify an arithmetic annual average of 0.15 mg/m^3 (IW 1) and a 98 % figure of 0.30 mg/m^3 (IW 2) “for protection against health hazards”. For “protection against significant detriment and nuisance”, the following figures for dust deposits (nonhazardous dusts) are prescribed: 0.35 g m^{-2} d^{-1} (IW 1) and 0.65 g m^{-2} d^{-1} (IW 2). The VDI commission for air pollution recommends the following maximum immission concentrations (MIK values): 1-a average: 0.100 mg/m^3, 24-h average: 0.250 mg/m^3, 3-h average: 0.500 mg/m^3. The following standard figures for simultaneous exposure to sulfur dioxide and airborne dust are laid down by the WHO: total suspended particulates (24-h figure): 0.120 mg/m^3, thoracic particles (deposition characteristics 50 % < 10 µm, 24-h figure): 0.070 mg/m^3 [48], [50], [62].

3.3.6. *Lead*

Lead is one of the most extensively investigated pollutants both in the environment and the workplace. There have been many investigations into the occurrence of lead in the various environmental media (air, water, soil, and food) and into the toxicity of lead to humans and animals. These are documented in the literature in a large number of comprehensive reports.

In the general population of Germany, the most important source of lead pollution is food. The daily intake has been estimated by the registry and advisory center for environmental chemicals of the German Health Office (ZEBS). The figure for men is 147.2 µg/d (1.03 mg/week), and for women 104.22 µg/d (0.73 mg/week). Of this, ca. 5 – 10 % is absorbed in the digestive tract by adults, while small children have an higher absorption rate amounting to ca. 50 % [64].

Of the total lead absorbed by adults (in air, food, and drinking water), the fraction absorbed by inhalation is ca. 17 – 25 %. Because of the higher lead absorption rate in the digestive systems, this figure is much lower for children (2 – 3 %).

Lead absorption by the human organism depends on the solubility of the lead compounds and the composition of the food. Deficiencies of calcium and vitamin D increase the absorption. The amount of inhaled lead-containing dust taken up by the organism is determined by the deposition, elimination, and absorption of the inhaled dust particles. It is assumed that 90 % of inhaled lead is absorbed.

The absorbed lead first enters the blood, and is distributed among the various organs and tissues. Approximately 90 % of the lead in the blood is bound to components of the erythrocytes. Lead inhibits various enzymes and thus affects several stages of hemoglobin synthesis. Several precursors of hemoglobin appear in the blood in increasing amounts, and are excreted in the urine (e.g., δ-aminolevulinic acid and coproporphinogen-III). Effects of lead on the erythrocyte membrane and reduction of the lifetimes of erythrocytes have also been described.

Lead is mainly accumulated in the bones. It can pass through the placenta and into the fetal blood circulatory system. Lead can also pass through the blood – brain barrier to a small extent, especially in children, in whom this barrier is not fully formed. The excretion of lead takes place via the feces and kidneys, a smaller fraction being eliminated via the hair and nails.

Acute intoxication is rare, as most lead compounds are sparingly soluble. Symptoms such as vomiting, colic, constipation, and acute kidney failure occur. Sometimes, lead encephalopathy is diagnosed, which leads to vomiting, apathy, vertigo, coordination disturbances, hyperactivity, and other effects.

The best known effects of chronic lead intoxication include weakness, loss of appetite, sleeplessness, nervousness, constipation, headache, muscular and joint pains, shivering, encephalopathy, and colic. Objective signs include pallor, weight loss, anemia, increased excretion of δ-aminolevulinic acid in the urine, increased blood lead level, decreased level of δ-aminolevulinic acid dehydrase in the blood, and changes in peripheral nerve conduction velocity.

Many investigations into damage to the central and peripheral nervous system caused by exposure to lead in the course of employment or from the environment have been carried out. There is a clear correlation between increased exposure to lead in the prenatal period and/or in early childhood and neuropsychological effects such as hyperactivity, fine motor disturbances, and reduction in intelligence and learning ability.

In the typical exposure situation of the general population, the following observed effects can be correlated in quantitative terms with the lead concentration in whole blood (internal lead burden). At lead concentrations of > 10 µg/100 mL in the

blood of children and > 15 µg/100 mL in adults, the first effects that appear are changes in the biosynthesis of hemoglobin by inhibition of certain enzymes. At blood concentrations of > 30 µg/100 mL, there is a statistically significant increase in arterial blood pressure. In children with blood lead concentrations of > 20 µg/100 mL, statistically significant impairment of individual functions of the CNS can be detected in neuropsychological tests. Impairment of fetal and infant development becomes statistically significant at concentrations of >10 to 15 µg/100 mL [65], [66].

Lead concentrations in the blood of the general population in Germany lie between 6 and 7 µg/100 mL. Lead concentrations of > 15 µg/100 mL are observed in only <1 % of the population. The WHO requires that 98 % of the normal population of adults and children in Europe should have a lead concentration in the blood of < 20 µg/100 mL [67].

There is no evidence of carcinogenic or cocarcinogenic effects of lead on humans, although the appearance of cancer in animals is observed at high doses. Mutagenic effects (chromosome aberrations) can occur with lead intoxication. Apart from its toxic effect on the fetus, there is no evidence that lead has teratogenic properties. In Germany, the TA-Luft Regulations for lead and inorganic lead compounds as components of airborne dusts “for protection against health hazards” specify an arithmetic annual average of 2.0 µg/m^3 (IW 1). For “protection against significant detriment and nuisance”, the figure 0.25 mg m^{-2} d^{-1} is specified as the IW 1 value for lead and inorganic lead compounds. The VDI commission has prescribed the following maximum immission concentrations (MIK values): 1-a average: 1.5 µg/m^3, 24-h average: 3.0 µg/m^3. The WHO recommends a standard range of 0.5 – 1.0 µg/m^3 [48], [50], [68].

3.3.7. *Cadmium*

The heavy metal cadmium is a nonessential trace element. It is absorbed orally and by inhalation, skin absorption being practically insignificant. Absorption of cadmium by the German population is mainly through food. According to information provided by the registry and evaluation center for environmental chemicals in the German Health Office (ZEBS) for the year 1984, the average cadmium intake via food by men was 34 600 ng/d (0.242 mg/week) and by women 26 900 ng/d (0.189 mg/week). The amount taken in via respired air is small, and is estimated at ca. 40 – 50 ng/day. Smoking 20 cigarettes per day results in a cadmium absorption of ca. 360 – 2200 µg/a. In food cadmium is mainly chemically bound to proteins [64].

The effects of cadmium depend on the quantity of cadmium absorbed into the blood. The absorption rate by the stomach and intestines is usually ca. 5 %, but this can be higher in cases of iron-deficiency syndromes. In contrast, cadmium entering the alveolar region of the lungs by inhalation is almost completely absorbed.

Cadmium has a marked tendency to accumulate in the human organism, mainly in the kidneys and liver. Thus, cadmium concentrations in the liver and kidneys increase with increasing age, and also in the blood and the urine. The most important factor is cigarette smoking. Cadmium concentrations in the blood of smokers are 3 – 5 times as high as those for nonsmokers, and cadmium concentrations in the renal cortex of smokers are ca. twice those for nonsmokers.

The health effects of increased chronic cadmium exposure in the workplace and the environment consist mainly of disturbances to kidney function, increase in arterial blood pressure, and the production of bronchial carcinomas.

The toxic effect of cadmium on the kidneys is mainly a result of the increase in the cadmium concentration in the kidney tissue. An early symptom is the increased excretion of low molecular mass proteins in the urine due to a disturbance to reabsorption in the proximal tubular section (tubular proteinuria). The diagnostic criterion is the increased excretion of β_2-microglobulin and retinol-binding protein. As well as tubular proteinuria, cadmium-induced glomerular proteinurias also occur, characterized by the excretion of high-molecular proteins. This symptom is very probably due to the deposition of immune complexes in the blood capillaries of the glomeruli [40].

If cadmium levels in the renal cortex exceed 200 µg/g, the first indications of a tubular proteinuria can appear in susceptible persons. At concentrations of > 250 µg Cd/g tissue, the appearance of a tubular proteinuria can be expected in 50 % of exposed persons.

Animal experiments have shown that the cardiovascular system is also sensitive to cadmium. Increase in blood pressure and myopathic heart damage can occur without any sign of damage to the kidneys. There are no corresponding results for humans at present. Lung and liver damage, anemia, and changes to the mineral balance of the bones (itai-itai disease) are also known.

There is no evidence of teratogenic effects of cadmium on humans, probably due to the low permeability of the placenta to cadmium. Information on the mutagenic effects of industrial or environmental exposure is contradictory, although genotoxic changes to human and animal cells can be caused by cadmium salts.

It is considered certain that a number of cadmium compounds show carcinogenic potential after inhalation. The German MAK Commission classifies cadmium, cadmium chloride, cadmium oxide, cadmium sulfate, cadmium sulfide, and other compounds that could enter the human organism (in the form of respirable dusts/aerosols) as materials with a definite carcinogenic effect (Group II A 2). Orally ingested cadmium, however, has no carcinogenic effect [69].

The German TA-Luft Regulations for cadmium and inorganic cadmium compounds as constituents of airborne dust specify an arithmetic annual average of 0.04 µg Cd/m^3 (IW 1) “for protection against health hazards”. For “protection against serious detriment and nuisance”, the figure for cadmium and inorganic cadmium compounds is 5 µg m^{-2} d^{-1} (IW 1). The WHO recommends that in urban and industrial areas, cadmium concentrations of 0.01 to 0.02 µg/m^3 can be tolerated. However, any increase in existing concentrations should be avoided so as to minimize the entry of cadmium into the food chain via deposition of dust. The Länder committee for immission protection (LAI) gives a “unit risk” for cadmium of 1.2×10^{-2} and an orientation figure of 1.7 ng/m^3. This figure represents the upper limit of background concentration in

rural areas in Germany, and is regarded as a standard for future immission reductions in urban areas [48], [50], [70].

3.3.8. *Arsenic*

Arsenic is a metalloid which is ubiquitous in the earth's crust in various forms. Toxicologically, inorganic arsenic compounds, organic arsenic compounds, and arsenic hydride (arsine) must be considered separately.

Arsenic is mainly ingested orally by humans in food and drinking water, but is also inhaled. The extent of absorption depends on the type of arsenic compound. Arsenic can also be absorbed through the skin. Organic arsenic compounds are ingested mainly during the consumption of fish, mussels, and crustaceans, the main compounds concerned being arsenobetaine, arsenocholine, and trimethylarsonium lactate and its derivatives.

Arsenic is rapidly transported within the body by the blood. It becomes distributed in human tissue in varying concentrations, being more concentrated in the skin, hair and nails, the lungs, the bones, and the brain. Inorganic arsenic compounds in the human body are largely methylated to dimethylarsinic acid, and to a lesser extent to methylarsonic acid. These methylated compounds are excreted more rapidly in the urine, and are less toxic. The excretion of arsenic is mainly performed by the kidneys, ca. 75 % of the arsenic in the urine being present as dimethylarsinic acid and a lower percentage as monomethylarsonic acid and inorganic arsenic.

The toxic effect of arsenic is mainly due to its ability to form covalent bonds with thiol groups. Various enzymes, such as monooxidase, urease, glucose oxidase, choline oxidase, can be inhibited by arsenic. Acute effects, chiefly on the gastrointestinal tract, are only likely with high doses. A dose of 70 – 180 mg arsenic trioxide is fatal for humans. The main symptoms of acute intoxication are difficulties in swallowing, abdominal pain, nausea, vomiting, chest pains, and watery diarrhea. Inorganic arsenic compounds, especially the trivalent oxides and chlorides, cause irritation of lungs and skin.

Chronic arsenic intoxication leads to disturbances to the peripheral and central nervous system, and lesions to skin and mucous membranes. Skin lesions include irregular pigmentation of the skin (melanism and leucoderma), hyperkeratosis, the appearance of diagonally striped white fingernails (Mees line), and warts. Damage to the mucous membranes mainly takes the form of conjunctivitis, nasopharyngeal catarrh, perforations of the nasal septum, bronchitis, diarrhea and constipation, and stomach cramps.

Effects on the PNS take the form of paraesthesia, motor disfunction, and a decrease in nerve conduction velocity. Lassitude and apathy, and more rarely encephalopathy indicate damage to the CNS. The optic nerves and the organ of balance can also be affected. The liver can become inflamed, and morphological changes such as cirrhosis and carcinoma can occur. Other effects related to exposure to arsenic have been observed, including damage to the heart (ECG changes), disturbance of red corpuscle production, (anemia and agranulocytosis), allergic contact dermatitis, and peripheral vascular disorders, leading to gangrene (black foot disease).

Indications of long-term occupational or environmental exposure include hematological, dermatological, and neurological symptoms. The critical threshold dose for a daily intake of arsenic is stated by various authors to be 400 µg/d. Inhalation of arsenic can lead to increased incidence of cancer of lung and skin, liver carcinoma, and tumors of the brain and nervous system. Oral ingestion mainly leads to skin carcinoma [40].

Arsenic has a teratogenic effect, as it can penetrate the placenta of both animals and humans.

The carcinogenic effect of inorganic arsenic on the human skin, lungs, and occasionally the liver has been demonstrated by epidemiological studies. It is explained by the inhibition of repair processes. Possibly, the phosphate groups of nucleotides are replaced by arsenate, as the two ions are of similar structure. Organic arsenic compounds do not appear to have a carcinogenic effect. The available data to some extent show dose – effect correlations for lung cancer (bronchial carcinoma) due to inhalation and for skin cancer due to oral ingestion.

Immission limit values are not specified for arsenic either in the TA-Luft Regulations or in the Air Quality Guidelines of the WHO. The Länder Committee for Immission Protection (LAI) gives a “unit risk” for arsenic of 4×10^{-3} and an orientation value of 5 ng/m^3. The latter figure represents the upper limit for the background concentration in rural areas of Germany, and can be used as a measure for future immission reductions in densely populated areas [70].

Inorganic arsenic compounds are essentially negative in point mutation tests, but have been demonstrated to be effective inducers of chromosome aberrations and sister chromatid exchanges. Chromosome changes were also observed in the lymphocytes of therapeutically or occupationally exposed persons.

3.3.9. *Benzene*

Benzene is the simplest aromatic hydrocarbon and is used as a solvent for a wide range of substances. It occurs in nature only in very low concentrations, e.g., as a constituent of crude oil (max. 0.4 g/L). It can also be formed by the incomplete combustion of organic compounds. In Germany, the main source of the benzene to which the population is exposed in the outdoor air is traffic.

The amount of benzene absorbed by the population of densely populated areas can be 200 µg/day, and can reach 600 µg/day in regions close to benzene emitters. Benzene absorption can also occur through smoking (20 cigarettes per day corresponds to a maximum of 600 µg), and can sometimes be due to food sold in gas stations (up to 5 µg/d) [71].

Prolonged inhalation of benzene leads to ca. 50 % absorption, oral ingestion probably to 100 %, and skin contact to <0.2 %. It is distributed throughout the organism, and becomes concentrated in fat-containing organs. Retained benzene is eliminated unchanged to a very variable extent by respiration (depending on the exposure concentration and individual circumstances) or is oxidatively metabolized and excreted with the urine.

The carcinogenic effect results from the metabolization of benzene to benzene epoxide by the monooxigenases in the endoplasmatic reticulum. Benzene epoxide can be converted nonenzymatically to phenol, but can also be metabolized by enzymatic action to catechol. Other metabolites include hydroquinone and hydroxyhydroquinone, benzyl glycol, and *trans-trans*-muconic acid. Also, a reaction of benzene epoxide with glutathion mediated by glutathion-*S*-transferase can occur. This thioether, after further metabolization, is then excreted as phenylmercaptic acid in the urine. Benzene epoxide can also react nonenzymatically with nucleic acids (to nucleic acid adducts, e.g., *N*-7-phenylguanine). In both humans and animals, the principal metabolite of benzene is phenol, which is mainly excreted in the urine in conjugated form. The ultimate toxic and carcinogenic metabolites of benzene are the quinones and hemiquinones [72].

Like most solvents, benzene has a depressant effect on the CNS. Local irritant effects on the skin and mucous membranes can occur. The most important effect of benzene is damage to the blood-forming system, especially on long-term exposure. The classical symptoms of acute and chronic benzene intoxication are generally only observed at very high or medium concentrations and usually after prolonged exposure. The immission concentrations normally present in the environment are insufficient to cause these symptoms. It is unanimously accepted that chronic exposure to benzene can lead to a very rapidly accelerating depression of all bone marrow functions, which then gives rise to changes in the peripheral blood picture. The various bone marrow functions can be damaged either simultaneously, in succession, or in isolation.

There is some disagreement over the question whether damage to bone marrow functions caused by chronic exposure to benzene is a precondition for the appearance of leukemia. The more recent view is that, in addition to the frequently described acute myeloid leukemia in epidemiological studies, there are also indications of an increased occurrence of chronic myeloid and chronic lymphatic leukemias, and a dose-dependent increase in lymphatic and hematopoietic neoplasms.

In vitro and in vivo tests have given no indication of point mutations due to benzene. However, numerical and structural chromosome aberrations were observed in exposed humans and in animal experiments. Carcinogenic effects in rodents (leukemias, lymphomas, and an increase in the various types of tumor and tumor locations) could be found in long-term inhalation experiments. However, high concentrations were required.

Immission limit values are not prescribed either by the TA-Luft Regulations or the Air Quality Guidelines of the WHO. Epidemiological studies gave unit risk estimates of 6×10^{-6} to 20×10^{-6}, with the median figure of 9.2×10^{-6}. The LAI gives 9×10^{-6} as the unit risk, and an orientation figure of 2.5 µg/m^3. This figure represents the upper limit of the background concentration in rural areas of Germany, and is the standard for future immission reductions in densely populated areas [70].

3.3.10. *Polycyclic Aromatic Hydrocarbons*

Polycyclic aromatic hydrocarbons (PAH) are formed pyrolytically in all incomplete combustion processes and in the low-temperature carbonization of organic materials. The relative concentrations of the many types of PAH (PAH profiles) mainly depend on the extent of heating. When different organic materials are pyrolyzed, the profiles obtained at a given temperature are very similar. Thus, as a general rule for the assessment of the carcinogenic hazard due to PAH in the open air, it is assumed that, as in the ideal case, the PAH profiles are identical, and that the concentration of an individual PAH can be used as a measure of the carcinogenic potential of the whole group. Therefore, the assessment of PAH concentrations in the air is usually based on the parameter benz[*a*]pyrene (BaP), as the most experience is with this substance. However, the BaP concentration in cigarette smoke or diesel engine emissions is not suitable for estimating the carcinogenic potential of the PAH in these media.

Compounds containing at least four rings are particularly relevant to the environment, as a number of these have carcinogenic effects. PAH have been detected in many vegetable and animal foodstuffs. Particularly high BaP concentrations are found in roasted or grilled products. Various vegetables such as kale, lettuce, carrots, spinach, and some types of grain sometimes contain high concentrations of PAH.

The absorption of PAH takes place mainly by the oral route (in food), while absorption by inhalation is almost exclusively associated with particles. The daily amount of BaP ingested in food in Germany is thought to be 1000 – 10 000 ng per capita. The daily intake by inhalation is estimated to be 10 – 200 ng per capita. Ingestion via drinking water is negligibly small, and cutaneous absorption in general plays no role. The amount of BaP ingested orally is certainly greater than that absorbed by inhalation in terms of quantity, but the intake of particles by inhalation is of considerably greater significance because of the formation of bronchial carcinomas [70].

The PAH compounds adhering to the particles are partly dissolved in the lungs and metabolized there. The metabolites can act on the cells, but can also be taken into the blood and detoxified in the liver, or can be excreted unchanged, especially in the bile, via the gut. Only a very small proportion of the PAH compounds is excreted with the urine in either a metabolized or an unchanged state.

PAH compounds have an inducing effect on microsomal enzymes. Little is known of acute or chronic toxic effects of the most important PAH compounds. Clinical signs of intoxication first appear after comparatively high doses. For example, newborn mice after a subcutaneous injection of 30 000 ng dibenz[*a, h*]anthracene (= 15 mg/kg body weight) showed no acute effects. This shows that the carcinogenic effect predominates over other effects [73].

The mutagenic effects of some PAH compounds have been detected in many test systems. There is a good correlation between the results of in vitro mutagenicity tests and the carcinogenic effect. BaP has a toxic effect on rat and mouse embryos, and a reduction in the fertility of mice has been reported.

The carcinogenic effects (mainly skin and lung carcinomas in persons exposed to chimney soot and coal tar) have long been known, and the mechanism of the carcinogenic action of BaP has been well researched. In general, the most widely

accepted view is that it is not the substance itself that is active, but the reactive epoxides formed by microsomal monooxigenases. The epoxides are converted by epoxidases to *trans*-dihydrodiols, which are the final carcinogenic metabolites. In laboratory animals, the carcinogenic effect is independent of the mode of application, and systemic tumors were also observed in other tissues.

Immission limit values are not specified for PAH compounds or BaP either in the TA-Luft Regulations or the WHO Air Quality Guidelines. From the risk estimates based on epidemiological studies, a unit risk of 7×10^{-2} can be derived for BaP. The LAI specifies an orientation value of 1.3 ng/m^3 for BaP. This figure represents the upper limit of the background concentration in rural areas of Germany, and is a standard for future immission reductions in densely populated areas [70].

3.3.11. *Diesel Motor Emissions*

Diesel motor emissions (DME, diesel engine exhaust) consist of a large number (>1000) of gaseous and particulate substances. DME particles, due to their small diameter (median diameter: 0.2 – 0.3 µm), mostly reach the alveoli, but are then to the extent of ca. 50 % expelled in the exhaled air. The mass of diesel soot particles absorbed by inhalation by the general population can only be estimated at present. Exposure in the open air in rural areas is up to 1.5 µg/m^3, in densely populated areas 5 – 10 µg/m^3, and in regions close to the emitters 15 – 25 µg/m^3 [70].

Apart from the particles, which carry adsorbed organic substances, the main toxic components of DME are nitrogen oxides and aldehydes. The acute toxicity of DME is insignificant. In animal experiments, the inhalation of DME with high particle concentrations led to a reduction in lung clearance. In inhalation experiments, exposure of rats to DME caused benign and malignant lung tumors after exposures that were ca. 75 – 100 times as high as those in densely populated areas in the middle of the week.

The carcinogenic effect is clearly linked to the particle phase. The very low level of polycyclic aromatic hydrocarbons (PAH) in DME can account for at most 1 % of the carcinogenic effect.

Particles and particle extracts from DME exhibit a mutagenic effect in several in vitro and in vivo test systems. Although this demonstrated a genotoxic mechanism, other mechanisms are also under discussion.

Epidemiological investigations on persons heavily exposed to DME in the course of their employment have so far provided “limited evidence” for carcinogenic effects of DME on humans, because insufficient attention was paid to extraneous effects.

DME is classified as a substance definitely known to cause cancer (MAK III A 2), and is classified with the Group II cancer-producing substances (“serious hazard”) in the hazardous substance regulations. Based on inhalation experiments on rats, a unit risk of 7×10^{-5} has been derived [70].

3.3.12. *Dioxins and Furans*

Polychlorinated dibenzodioxins (PCDD) and polychlorinated dibenzofurans (PCDF) are tricyclic, almost planar, aromatic compounds with similar physical, chemical, and biological properties. Depending on the degree of chlorination a number of isomeric compounds (congeners) can exist. The theoretical possible number of congeners is 75 for PCDD, and 135 for PCDF. None of the congeners are produced industrially, except as analytical standards. PCDD and PCDF are formed only as undesirable byproducts of chemical and thermal processes, and enter the environment from many sources. Their persistence, buildup in the food chain, ubiquitous occurrence, and the marked toxicity of some congeners of both groups can constitute a health hazard for humans. They are present as impurities at very low concentrations in many chemicals (e.g., pentachlorophenol) [40].

Adequate data are unavailable for most of the PCDD and PCDF congeners of toxicological significance. The most biologically active compound of the PCDD group is 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD or “Seveso” dioxin). This does not occur in isolation, but can be detected in PCDD/PCDF mixtures in a wide variety of compositions. The toxic potential of PCDD/PCDF mixtures is estimated as TCDD equivalent figures (TEq), derived partially from subchronic toxicity studies and from certain biochemical properties. TEq figures represent the relative toxicity of a mixture in terms of the toxic effect of 2,3,7,8-TCDD. The scientific basis for the TCDD equivalence factors (TEF) is that there is a common effect mechanism, and there is therefore a strict correlation between the binding of the various PCDD/PCDF compounds to the cytoplasmic arylhydrocarbon (Ah) receptors and the biological effects resulting from this. The following properties of PCDD and PCDF based on animal experiments were taken into account [74]:

1. The binding affinity to the Ah receptors
2. The ability to induce various enzyme systems
3. The toxic effects on certain cell cultures (e.g., keratinization)
4. The acute and chronic toxicity

The strongest counterargument is that the isomers so compared with each other differ strongly in their toxicological behavior, and this cannot be adequately represented by the TEF, and TEq figures are not suitable for estimating the potential cancer risk of exposure to PCDD and PCDF. Any statements made about the possible risk to the population from other effects must be made with considerable reservations, especially concerning long-term exposure to very low concentrations.

In the environment PCDD and PCDF are almost exclusively associated with fine dust, and hence can be absorbed by inhalation. However, the amount absorbed by inhalation is less than 5 % of the total. An inhaled volume of 20 m^3/d corresponds to an inhaled dose of 0.4 – 6 pg TEq per person per day. With 50 % deposition in the lungs and 100 % absorption, this represents 0.2 – 3 pg TEq absorbed per person per day [74].

The highest proportion of the daily intake of PCDD and PCDF by the general population comes from foodstuffs of animal origin. The average daily intake by an adult is estimated by BGA/UBA (1993) to be ca. 2 pg TEq/kg body weight. Bearing in mind variations in eating habits, an average intake by 4 – 9 year old children of 2 – 3 pg TEq/kg body weight can be derived. For one year old children, an average daily intake of ca. 4 pg TEq/kg body weight is calculated. Gastrointestinal absorption from foodstuffs is almost 100 %. Intake with drinking water is small [75].

2,3,7,8-TCDD is rapidly distributed in the organism, and causes systemic damage to various organs; it can cross the placental barrier. 2,3,7,8-TCDD affects lipid metabolism, vitamin A balance, and thyroid gland function. Some of these disturbances are due to binding to the Ah receptors and the resulting induction of various enzyme systems. Various glucuronide and sulfate conjugates have been shown to be metabolites. The metabolism takes place through P450-dependent enzymes. There is a high percentage of nonmetabolized 2,3,7,8-TCDD. The PCDD compounds are mainly eliminated in the feces. Dioxins accumulate in the fatty tissue and are mobilized in the milk of nursing mothers. Animal experiments and human experience have shown that excretion decreases with increasing degree of chlorination. The mechanism of excretion in humans is unknown. The half-life of PCDD in humans is 5 – 10 years, but only a few weeks in rats [76].

Acute and subchronic intoxication by TCDD-containing PCDD mixtures can be recognized from a large number of organ manifestations. The skin and liver are particularly affected by disturbance of the porphyrin and fat metabolism, and by the induction of mixed function oxidases. The PNS, CNS and immune system can also be damaged. Direct contact can cause lesions of the skin. TCDD has strong acute toxicity compared with PCB. Acute exposure is first followed by irritation of the eyes and the upper respiratory tract, sometimes accompanied by vertigo, nausea, and vomiting. In later stages, reddening and swelling of the affected parts of the skin can occur. Typical skin lesions known as “chloracne” develop. The most affected organ is the liver. Swelling and liver parenchyma damage occurs, leading to an increase in the transaminases in the blood. Neurological damage following TCDD exposure seems to occur more often than has generally been assumed up to now [74], [76].

Animal experiments indicate fetotoxic and teratogenic effects, and impairment of reproduction by TCDD is also known. Following maternotoxic doses, teratogenic effects are observed in mice, but fetotoxic effects in rats and monkeys. At present, there is no indication of teratogenic effects in primates. Animal experiments also indicate immunotoxic effects such as thymic atrophy and suppression of cell-mediated humoral immune responses. TCDD does not appear to be mutagenic in the Ames test. Absence of mutagenicity is also shown in many other in vivo and in vitro tests, the binding of TCDD to DNA being very weak. In exposed industrial workers, no indication of chromosomal damage has been found either.

The carcinogenic effect of TCDD following oral and parenteral application in animal experiments has been thoroughly investigated and neoplasms at multiple sites have been recorded. Carcinogenic effects of other PCDD or PCDF compounds are presently unknown.

Persons exposed in Vietnam to TCDD-containing herbicides or to TCDD in Seveso were not found to have any increase in chromosome damage. Comprehensive epidemiological studies in the United States, Sweden, Canada, and New Zealand did not provide any solid evidence for carcinogenic effects from the use of herbicides containing TCDD or PCDD as impurities. However, an increased incidence of stomach carcinomas was reported in exposed workers. More recent investigations of this group revealed a slight increase in the standardized mortality rate, but no statistically significant increase in the incidence of tumors. Case control studies of workers who had worked with TCDD-containing herbicides for some years revealed an increased incidence of rare soft tissue sarcomas (hemangiosarcomas). The apparent absence of a mutagenic effect, the lack of DNA adduct formation, and the tumor-promoting activity in two-stage models in liver and skin indicate that TCDD must be regarded as a nongenotoxic carcinogen. This allows the conclusion that a threshold of carcinogenicity exists, below which promotion is not maintained [74-77].

In view of the lack of any indication of a direct genotoxic effect, and assuming a threshold concentration for the promoting effect, a temporarily tolerable daily uptake has been derived by national and international authorities. A figure of 1 pg TEq/kg body weight has been proposed for Germany [74].

If, however, contrary to the present state of knowledge, it is assumed as a precautionary measure that there is no effect threshold, linear extrapolation from animal experiments with oral application of 2,3,7,8-TCDD yields a putative unit risk of 1.4 for inhalative exposure. Combination effects with other PCDD compounds were not included.

Immission limit values for PCDD/PCDF have neither been specified in the TA-Luft Regulations nor in the WHO Air Quality Guidelines. The LAI gives an orientation figure of 16 fg/m^3 for 2,3,7,8-TCDD. This figure represents the upper limit of the background concentration in rural areas of the Federal Republic of Germany, and is the standard for future immission reductions in densely populated areas [70].

3.4. Effects on Plants [78-81]

The effects of air pollutants on plants are of interest both from the point of view of their economic exploitation and because of their great ecological significance.

Before they act on plants, air pollutants are subject to the effects of a large number of fortuitous and nonfortuitous factors (weather, etc.). The plants themselves have defense mechanisms that can influence the progress and severity of the action of a pollutant. They react towards air pollutants with a specific resistance behavior of genetic origin, which is also affected by the plants' state of development at the time and by the external growth conditions. Since plants are open systems, they are highly sensitive towards foreign substances present in the air.

3.4.1. *Relationship between Immission and Effect*

A complex structure of relationships exists between immission and effect. The reaction of the plants depends primarily on

the presence of one or more immission components. The type and extent of the effect are essentially determined by the genetic structure, the growth stage of the plant at the time of exposure, and the modifying influence of various external factors. Depending on the severity and circumstances of the pollution, the stage of growth, and environmental conditions such as soil, weather or climate, and biotic effects, individual plants can suffer acute, chronic, or insidious damage. Plant communities react with changes in their composition and structure, up to complete destruction. The plants' economical and ecological viability can be affected, and eventually gene erosion by extinction of the species can occur.

Acute damage is mainly caused by the short-term effects of immissions at higher concentrations. This is manifested first on plant leaves by loss of turgescence and subsequent drying of the affected parts of the tissue. In general, a few days later, ivory colored, brown, red-brown, or blackish leaf necroses occur. Repeated effects of this kind weaken the vitality of plants. Severe, acute damage can lead to their complete destruction.

Chronic damage occurs after prolonged effects of low concentrations of immissions. Typical external signs include yellowing, or reddish-brown, turgescent marks on the leaves. In the course of continuing exposure, the symptoms of damage become more severe, causing decreased vitality, restriction of growth, and finally the death of the plant.

In addition to acute and chronic damage, erosive damage is also observed. This is produced by the action of acid fog or water-soluble deposits of reactive dusts. In these cases, the high ion concentrations that can be formed on moist leaf surfaces are very important.

Indirect damage can occur when air pollutants accumulate in soil penetrated by roots and change its properties as growth substrate (e.g., pH value). Damage can also be caused by absorption of accumulated substances through the roots.

Finally, immissions can cause a general reduction in the resistance of the plants towards plant diseases (e.g., from fungi and insects) and frost.

The solubility, reactivity, and state (gaseous or particulate) of the substance are the main properties that determine whether a pollutant can affect the plant surface on contact. The spectrum of activity is broad. Not all species and varieties of plants react in the same way to a harmful immission component. Also, some harmful substances produce specific reactions in certain plants. This peculiarity in the spectrum of effects on vegetation has been recognized from early times, and used to detect various air pollutants [82].

Effect Criteria. The large number of possible effects of air pollutants can be characterized by the corresponding effect criteria. These range from accumulation of harmful substances in the plants, disturbance of the physiological and biochemical processes in the cell, and submicroscopic changes to the cell organelles, to morphological changes to organs and impairment of the entire organism. On the level of a plant community, effects on structure and function, possibly including complete destruction, must be mentioned. Other effect criteria include reduced vitality, reduced yields, loss of quality, increased susceptibility to abiotic and biotic influences, and death of the entire plant. An overview of the criteria for the detection of the effects of immissions on plants is given in Table 4 [83].

Table 4. Criteria for determining the effects of immissions on plants [83]

Criterion	Level of investigation
Species spectrum	ecosystem
Abundance of species	biocenosis
	population
Growth form	population
Necroses	organism
Chloroses	organ
Leaf fall	
Biomass	
Accumulation of materials	
Photosynthesis	organism

carbohydrates, pigment	organelles
status, energy balance,	macromolecules
buffering capacity,	

mineral balance)

Proof of Effects. In addition to the measurement of emissions and immissions, the use of plants as information systems for the protection of the environment from air pollution is indispensable. To obtain a complete survey, it is essential that every effect should be determined on both higher and lower plants. However, in practice, this requirement can only be met to a certain extent. As a rule, relevant effects on the most representative plants possible are chosen [84]. Representative plants are those for which the effects are broadly comparable with those on other plants, or for which an effect can be predicted from another effect on one and the same plant. Since the many factors cause a wide variety of harmful effects, the causal relationship between air pollution and effects often cannot be established with certainty in field investigations. For the qualitative and quantitative determination of immission effects, standardized methods whose results enable reliable conclusions to be drawn have now been in use for some years [85-88].

Dose – Effect Relationship. Greenhouse and open land experiments under defined boundary conditions and observations in open land enable the relationship between immission concentration and effect to be described. As absorption of the pollutants usually precedes their effect, an attempt is also made to determine the relationship between these two parameters rather than a relationship between immission concentration and effect. The amount of pollutant taken up from the immission is defined as the immission dose (milligrams pollutant taken up per kilograms acceptor substance or milligrams pollutant taken up per squared meter acceptor surface) and as the immission rate (milligrams pollutant taken up per kilograms acceptor substance per unit time, or milligrams pollutant taken up per squared meter acceptor surface per unit time) (see VDI 2309, Sheet 1). The use of the terms immission dose and immission rate is subject to the limitation that the analytically determined concentration in an acceptor is always a function of the immission flow (see VDI Guideline 2450, Sheet 1), as well as being the result of absorption by other routes, and processes of growth, destruction, excretion, and redistribution in the organism.

Immission dose, immission rate, and immission concentration are known as immission values. The relationships determined between one of these values and its effects on plants is the basis for the establishment of maximum immission values by the VDI commission for air pollution. The aim and significance of these values, which give the decision maker the essential information for fixing limit values, are described in the VDI Guideline 2310, Sheet 1 [89].
Concentration/dose – effect relationships determined in gas exposure experiments on test plants can only be translated to open land relationships to a limited extent, as in climatic chambers, greenhouses, or other closed experimental arrangements, the changing immission concentrations of an open location and the varying meteorological growth factors such as light, temperature, air humidity, and wind can only be approximated. Under such “artificial” conditions, plants can react towards air pollutants more sensitively than in open land conditions [90]. Observations under natural open land conditions or in open land experiments also enable only approximate conclusions to be drawn about the relationship between exposure to a harmful substance and its effect. Furthermore, a generally valid derivation of the relationship between immission concentrations and effect cannot be obtained with certainty from observations in open land or from the results of open land experiments. This is because in the open air very variable air pollution occurs, several immission components normally being present. This leads to effects that are not comparable to specific damage by a single pollutant.

Open top chambers occupy a position somewhere between open land and climatic cabinets [91]. These large chambers, which are open at the top, are placed in the open air. The dose – effect relationship is determined experimentally by introducing air from outside to the test plants. In practice, the immission values are deduced by careful investigation of the results of one or all three methods. Responsibility for determining immission values lies with various working groups of the German Association of Engineers (VDI). The maximum immission values obtained are not limit values, but standard figures at which the risk of damage to vegetation can be limited.

3.4.2. *Effect of Individual Pollutants*

3.4.2.1. *Sulfur Dioxide*

Many publications deal with the effect of sulfur dioxide on plants. Important knowledge was obtained in the 1930s, especially in the United States and Canada. A bibliography by the VDI for 1974 – 1978 lists almost 250 references [92].

Uptake and Plant Reaction. Sulfur is an essential nutrient for plants. It is taken up via the roots from the soil in the form of SO_4^{2-} ions. However, plants can also use the SO_2 from air pollutants to make up for sulfur deficiency.

To affect the leaf [93], SO_2 must penetrate via the stomata into the leaf tissue and cells. This leads to the formation of sulfite and hydrogensulfite ions as dissolved products. A significant part of the absorbed SO_2 is oxidized to sulfate. In general, it is known that damage can consist of reduced activity of various enzymes or increased peroxidase activity and breakdown of chlorophyll. However, these reactions are not specific to the effects of SO_2, and can also result from the action of ozone or phytopathogenic fungi. Reactions specific to SO_2 include the breakdown of tryptophan or indolylacetic acid and the rupture of S – S bonds in proteins.

Photosynthesis reacts to the effects of SO_2 with high sensitivity. However, any retardation of this process can be compensated to a certain extent by an increase in the concentration of CO_2.

Detoxification reactions include neutralization of the acid sulfite and oxidation to sulfate and the formation of organic sulfur compounds. This explains why the concentration or, more accurately, the SO_2 uptake per unit time determines the extent of damage. The physiological activity of a plant is therefore a decisive parameter for the risk of acute damage. This is at its greatest in the spring and summer months, and especially in the morning hours. Chronic damage, mainly nonspecific in character, is caused by the gradual accumulation of sulfur until the damage threshold is exceeded.

Plant species vary in their sensitivity towards SO_2. In general, plants are classified as very sensitive, sensitive, and less sensitive. However, even the most resistant plant species are not totally resistant to SO_2. The resistance behavior of various economically important cultivated plants is given in Table 5 [94].

Table 5. Resistance of plants to SO_2

Very sensitive plants	Sensitive plants	Less sensitive plants
Deciduous trees and bushes		
Walnut (*Juglans regia*)	Lime (*Tilia spec.*)	Plane (*Platanus spec.*)
Red currant (*Ribes rubrum*)	Red beech (*Fagus silvatica*)	Oak (*Quercus spec.*)
Gooseberry (*Ribes uva-crispa*)	Hornbeam (*Carpinus betulus*)	Poplar (*Populus spec.*)
	Apple (*Malus domestica*)	Maple (*Acer spec.*)
	Hazelnut (*Carylus avellana*)	Alder (*Alnus spec.*)
		Lilac (*Syringa vulgaris*)
		Woad (*Salix spec.*)
		Robinia (*Robinia pseudoacacia*)
		Birch (*Betula spec.*)
		Cherry, plum (*Prunus spec.*)
		Vine (*Vitis vinifera*)
		Rhododendron (*Rhododendron spec.*)
Conifers		
Fir (*Abies spec.*)	Pine (*Pinus silvestris*)	Black pine (*Pinus nigra austriaca*)
Spruce (*Picea spec.*)	Weymouth pine (*Pinus strobus*)	Arbor vitae (*Thuja spec.*)
Douglas fir (*Pseudotsuga menziesii*)	Larch (*Larix sepc.*)	Yew (*Taxus baccata*)
		Juniper (*Juniperus spec.*)
		Japanese Cypress (*Chamaecyparis spec.*)
Agricultural and horticultural plants		
Clover (*Trifolium spec.*)	Barley (*Hordeum vulgare*)	Potato (*Solanum tuberosum*)
Lucerne (*Medicago sativa*)	Oats (*Avena sativa*)	Tomato (*Lycopersicon esculentum*)
Lupin (*Lupinus spec.*)	Rye (*Secale cereale*)	Maize (*Zea mays*)
Vetch (*Vicia sativa*)	Wheat (*Triticum sativum*)	Turnips (*Beta vulgaris ssp.*)
Horse bean (*Vicia faba*)	Lettuce (*Lactuca sativa*)	Cabbage (*Brassica oleracea ssp.*)
Spinach (*Spinacia oleracea*)	Bean (*Phaseolus spec.*)	Carrot (*Daucus carota*)
Pea (*Pisum sativum*)	Rape (*Brassica napus*)	Strawberry (*Fragaria chiloensis*)
		Garlic (*Allium spec.*)
Ornamental plants		
Begonia (*Begonia spec.*)	Dahlia (*Dahlia variabilis*)	Rose (*Rosa spec.*)
Vetch (*Lathyrus odorata*)	Geranium (*Pelargonium zonale*)	Gladiolus (*Gladiolus spec.*)
	Petunia (*Petunia hybrida*)	Tulip (*Tulipa gesneriana*)
	Carnation (*Dianthus caryophyllus*)	Iris (*Iris spec.*)
	Fuchsia (*Fuchsia hybrida*)	Narcissus (*Narcissus pseudonarcissus*)
		Chrysanthemum (*Chrysanthemum leucanthemum*)
		Heather (*Calluna vulgaris*)

This classification is carried out by using as effect criteria visible damage and impairment of physiological vitality, adversely affecting the economic exploitation of the plant. Results of open land observations and experiments in combination with continuous and noncontinuous SO_2 measurements in the air yield the essential information for the establishment of maximum immission parameters for the protection of vegetation [94]. In risk assessment from epidemiological data on the effects of SO_2, the presence of other pollutants is not taken into account. The composition of the pollutants, their mixing ratio in the air, and also hitherto unrecognized factors can give rise to synergistic or additive

effects on plants. Various findings concerning the combined effects of SO_2 with NO_2, HCl, HF, ozone, and heavy metals are reported in the literature.

Relationship Between Concentration/Dose and Effect. Investigations into exposure to SO_2 under experimental conditions have shown that most plants show considerably greater compatibility than in open land conditions [94]. In the last decade, short-term high SO_2 concentrations have in general been limited to accidental releases, so that there is now more interest in the harmful effects of SO_2 on long-term exposure to low concentrations. Investigations into tolerance thresholds carried out in various countries give figures of 0.04 mg/m^3 for very sensitive plants, >0.08 mg/m^3 for sensitive plants, and up to 0.12 mg/m^3 for less sensitive plants.

There are many publications on the subject of combined effects, especially of SO_2 and ozone. It is often difficult to link visible symptoms of damage with the pollutant causing them. The nature of the effect is also dependent on the degree of exposure to the pollutant. A combination of SO_2 and ozone in a concentration at which each individual gas would cause serious leaf damage often has an antagonistic effect. At lower concentrations, synergistic effects predominate [95]. The effect of combining SO_2 with other gases, according to available knowledge, can be antagonistic, additive, or synergistic. The effect of a combination of substances depends on the ratio of the concentrations of the two components and their absolute concentrations [92].

Threshold values for SO_2 for the protection of vegetation have not yet been established. The VDI Guideline 2310, Sheet 2, of Aug. 1978, in which the maximum immission values for SO_2 for the protection of vegetation are specified has not so far been finalized.

3.4.2.2. *Hydrogen Fluoride*

As early as the 1800s, hydrogen fluoride was known to be a pollutant harmful to plants. It has the strongest phytotoxic action of all gases. The gaseous compounds SiF_4 and H_2SiF_6 are as harmful as HF, while particulate fluorine compounds are less so. Among the many publications on the effect of fluoride immissions on plants. There is a comprehensive review of the subject in VDI Guideline 2310, Sheet 3 [96].

Plant Uptake and Plant Reaction. Plants can take up fluoride both from the air and from the soil. The fluoride absorbed from the soil is carried to the parts of the plant above ground by transpiration. Transport via the xylem and plasmatic transport causes fluoride to be deposited preferentially in the tips or edges of the leaves.

Absorption of gaseous fluorine compounds from the air takes place mainly through the stomata of the leaves. Particulate immissions containing water-soluble fluorides can cause local erosive damage, mostly of the epidermis, on plant surfaces covered with dew. The absorption of gaseous fluorine compounds through the stomata is influenced by the width of the openings, which depends on, e.g., light, temperature, atmospheric humidity, and the state of development of the plant. Damage to the plants takes place by direct action, which is concentration-dependent, and indirectly by accumulation in the leaf, especially in the tips and edges. In these parts of the tissue, the amount of fluoride deposited is often many times higher than in the other parts of the plant. Because of the marked concentration effects, plants are also damaged by low concentrations if they are exposed to the pollutant for prolonged periods. Increased fluorine contents are usually a sign of the effects of fluorine compounds, and are therefore an important diagnostic criterion.

Variable sensitivity towards fluoride immissions can occur with different plant species, varieties, and origins. However, absolute resistance does not exist. The species-specific resistance differences are utilized to build up resistant series and resistant groups. For practical protection against immissions, it is convenient to divide plant species into the groups “very sensitive”, “sensitive”, and “less sensitive” [96]. The very sensitive species include spruce, vines, apricots, onions, gladioli, and other bulbs, and corms. The group of sensitive plants includes pines, firs, larch, beech, walnut, cherry, lucerne, grain, fodder barley, strawberries, and caryophyllaceous plants. The less sensitive plants include yew, black pines, maple, oak, birch, pear, potatoes, tomatoes, turnips and beet, geraniums, and ornamental compositae. However, the various varieties and subspecies within a group (e.g., the gladioli) can differ greatly in sensitivity among themselves.

Relationship between Concentration/Dose and Effect. Extensive documentation of the relationship between HF concentrations in the air and the effects on higher plants, as a basis for hazard predictions, is provided in the VDI Guideline 2310, Sheet 3. This contains results of experiments on exposure to gases, and data from open land observations. The relationship between immission and effect does not generally obey the quantitative law of erosion, which states that equal concentrations/doses cause equal effects. A demonstration of the difference in reaction between individual species was provided by gladioli and ponderosa pines that were exposed for 2 weeks in the vicinity of an aluminum works [97]. At an average HF concentration of 0.49 ppb, the gladioli showed a damage index (ratio of necrotized leaf tips to total length × 100) of 25.4, compared with 32.7 for the pines exposed to a concentration of 2.36 ppb (i.e., 5 times as high). The damage to the pines increased progressively with the concentration. The difference in reaction may essentially be caused by differences in the secondary deposition of the absorbed fluorine at the leaf edges and tips, and also by an effect on the diffusion resistance of the leaves.

The combination of fluorine compounds with other gaseous air pollutants can lead to increased, decreased, or unchanged fluorine accumulation in plants. At present, there is no consistent model that can account for the combined effects of HF with other gaseous components. However, it is possible to make qualitative predictions for certain boundary conditions [96].

Maximum Immission Values. The necessary preconditions for the derivation of maximum immission values for hydrogen fluoride in combination with other pollutants have not been fulfilled. Hence, the VDI Guideline 2310, Sheet 3, of December 1989, only gives results of gas exposure experiments and open land investigations in which the amount of harmful

substance was defined by the concentration and duration of its effect. Based on protection of the species and not of the individual, the maximum immission values for hydrogen fluoride are as follows (in µg/m^3):

Very sensitive plants	1.0 [a]	0.3 [b]	0.2 [c]
Sensitive plants	2.0	0.6	0.4
Less sensitive plants	7.5	2.5	1.2

[a] Exposure time: 1 d

[b] Exposure time: 1 months

[c] Exposure time: 7 months (vegetation period)

3.4.2.3. *Hydrogen Chloride and Chlorine*

The harmful effects of hydrogen chloride on plants are comparable to those of SO_2. In gas exposure experiments, it was found that the lower limit for damage to sensitive plants after prolonged exposure lies between 0.1 and 0.3 mg/m^3.

The results of HCl gas exposure experiments cannot be applied directly to open land conditions, as the atmosphere often contains large quantities of neutral chlorides (e.g., salt) in the form of aerosols as well as HCl. These cannot be distinguished from HCl by measurement techniques. Salt aerosols, e. g., in coastal regions, can cause plant damage, but their effect is small compared with that of HCl. Laboratory gas exposure experiments have shown that salt aerosols have less than 10 % of the harmful properties of HCl aerosols or HCl gas [98].

The VDI Guideline 2310, Sheet 4, gives the following limit values (mg/m^3) based on gas exposure experiments lasting 24 h and 1 month respectively:

Very sensitive plants	0.80	0.10
Sensitive plants	1.20	0.15

Very sensitive plants include vines, spruce, horse beans, and berberis, while sensitive plants include red beech, pine, oats, and primulas, and the less sensitive plants include oak, blue spruce, kale, and fuchsia.

Chlorine is as harmful as hydrogen chloride, but is only of relatively small significance for vegetation because of its very rare occurrence.

Several species of pine showed needle necroses after exposure to 3 mg Cl_2/m^3 for 3 h [98]. Very sensitive herbaceous plants, including lucerne, tobacco, and radish were damaged after exposure to as little as 0.3 mg/m^3 for 2 h.

3.4.2.4. *Nitrogen Dioxide and Ammonia*

Nitrogen dioxide is the most harmful of the oxides of nitrogen, but it is less phytotoxic than other acidic gases. Nevertheless, prolonged exposure of sensitive plants to >0.4 mg NO_2/m^3 leads to growth retardation and signs of chlorosis. In gas exposures of several hours, concentrations of 10 – 20 times this figure are necessary to cause any damage.

The VDI Guideline 2310, Sheet 5, for sensitive plants such as maple, spruce, wheat, and fuchsia, gives a limit value of 0.35 mg/m^3 as the mean figure for the vegetation period, and 6 mg/m^3 for a single exposure of 30 min. For very sensitive plants such as apple, birch, larch, oats, and rose, slight damage is possible at these concentrations. Less sensitive plants include beech, yew, brassicas, and gladioli.

Ammonia is absorbed through the stomata of the leaves, and can be used for protein synthesis in the cells provided no cell damage is caused at the concentration present. Damage caused by ammonia differs from that caused by acid gases in that the leaves and needles first turn brownish-red, later dark brown, and finally black. Relatively little is known about the dose – effect relationship. Gas exposure experiments by the LAI showed that the first signs of damage to cress, a sensitive plant, were visible after exposure to 1 mg NH_3/m^3 for 2 – 3 days [99].

3.4.2.5. *Hydrogen Sulfide*

Hydrogen sulfide was formerly thought to be a gas that causes relatively slight plant damage, plants in general being regarded as much more resistant to H_2S than to SO_2 [78 p. 99]. Following more recent investigations, this conclusion must be amended. Exposure of spinach and peas to 1.2 mg H_2S/m^3 led to an increase in transpiration which caused drooping of the leaves, often followed by the formation of necroses [101]. Also, the efficiency of photosynthesis can be reduced, leading to a reduced formation of biomass.

H_2S has been reported to be even more harmful than SO_2 [102]. In a gas exposure test lasting 14 d, damage occurred even at concentrations of 0.45 mg H_2S/m^3 in various garden plants (radishes, dwarf beans, and cress) comparable to that

produced by SO_2 at 0.70 mg/m^3. Only red clover was more sensitive to SO_2 than to H_2S. However, it can be assumed that H_2S damage to vegetation only occurs on accidental release from industrial installations.

3.4.2.6. *Ethylene*

Ethylene is produced in the plant itself. It acts as a ripening hormone, and at the same time automatically stimulates increased ethylene production. Anthropogenic ethylene concentrations are also effective in extremely low concentrations. This differentiates it fundamentally from the other harmful gases. Necroses hardly ever occur. Instead, inhibition of the lengthwise and surface growth of leaves occurs, abnormal ripening such as the curling of younger leaves and the downwards curling of the leaf stalks (epinastia), dying off of end buds, premature aging, yellowing, and leaf fall.

The following results are selected from the many gas exposure investigations: 0.1 mg C_2H_4/m^3 caused a 30 % reduction in the dry substance of dwarf beans and radishes after 14-d exposure. The blooms of ornamental plants lost their color at the same concentration after the second day. The first reactions can occur at a concentration of little more than 0.01 mg/m^3. As well as the above plant species, peach, clover, tomatoes, peas, potatoes, and roses are sensitive to ethylene. However, relatively insensitive plants include the monocotyledonous varieties, with the exception of orchids and the conifers, which are very sensitive.

The flat dose – effect curves are striking. An effect appears immediately at very low concentrations, but increases only very slowly with increasing concentration. This makes it very difficult to establish immission threshold values [99]. A comprehensive study of the effect of ethylene and other hydrocarbons on higher land plants was carried out by the Deutsche Gesellschaft für Mineralölwissenschaft und Kohlechemie (German Association for Mineral Oil Science and Carbon Chemistry) [100].

3.4.2.7. *Ozone and Other Photooxidants*

Ozone has a strong phytotoxic effect on plants. It is a component of photochemical smog, being an intermediate product of photooxidation which eventually leads to the production of the strongly phytotoxic peroxyacetyl nitrate as well as other smog components. The photochemical oxidants are taken up exclusively by direct absorption from the air. In the absorption of ozone, it has been found that the stomatic resistance is a decisive factor, and determines the severity of the effect of the gas in each individual case [103]. The action of ozone leads to a change in the permeability of the cell wall, which leads to an increased loss of the dissolved substances in the cell. The efficiency of photosynthesis is reduced by ozone to a measurable extent, often before the appearance of visible damage. Plants react to ozone with varying sensitivity.

It is estimated that in the United States ca. 90 % of plant damage is due to photooxidants. The direct economic damage is mainly due to the effects on growth, yield, and quality. Plant products used as foods and feeds and ornamental plants show reduced yields, changes in the composition of the useful plant substances, and lower perceptible quality. Because photooxidants are always in gaseous form, damage to ornamental plants is also widespread in the United States [106].

Considerable damage is also reported in The Netherlands. The occurrence of damaging ozone concentrations in Germany was detected in many urban areas with the aid of highly sensitive indicator plants (e.g., the tobacco species Bel-W-3 or the small nettle). Also, the contribution of ozone to the so-called new forest damage is generally acknowledged. The phenomenon of extensive forest damage observed in the mid-1970s is linked to air pollution, e.g., by ozone, and is supraregional. A large range of effects appear over a narrow concentration range. Higher concentrations are found especially in the areas of Central Europe remote from sources of pollution and at higher altitudes. Moreover, ozone pollution has considerably increased [107].

The concentration – effect relationship is the subject of many investigations. In VDI Guideline 2310, Sheet 6 [95], air quality criteria for the protection of vegetation were derived from results from open land, climatic chambers, and greenhouses. According to this, plants react with varying sensitivity to the action of O_3. The more sensitive plants include apricot, walnut, Weymouth pine, lucerne, oats, lettuce, and tomato. The less sensitive plants include red beech, red oak, Norway maple, mustard, turnips, strawberries, celery, and cabbage lettuce.

Combination effects with other harmful substances are known in which the effects of ozone are intensified by the presence of, e.g., SO_2 and NO_2. However, in the present state of knowledge, it is not yet possible to quantify the effect of SO_2 and NO_2 on the overall effect.

The maximum immission concentrations for the protection of vegetation (see VDI Guideline 2310, Sheet 6) apply to O_3 as a single component acting for a brief period, i.e., 0.5 – 8 h. In general, very sensitive, sensitive, and less sensitive plants are protected up to concentrations of 320 µg/m^3, 480 µg/m^3, and 800 µg/m^3 respectively for an exposure time of 0.5 h. The concentration decreases with increasing exposure time, and, for a period of 8 h, is 70 µg/m^3, 160 µg/m^3, and 320 µg/m^3, respectively. There is no figure for prolonged exposure, as the necessary data are not available. The WHO specifies a figure of 60 µg/m^3 for the protection of vegetation for long periods, as average value for the vegetation period [108].

3.4.2.8. *Dust*

The term dust refers to particulate air pollutants of very heterogeneous composition. Their phytotoxic effect is considerably less than that of harmful gaseous pollutants. The direct effect of dusts depends very much on their solubility in water. Indirect effects on roots depend on the condition of the soil. Dust deposits on plant surfaces do not usually have a serious effect. However, damage to vegetation can be caused by salt, gypsum, cement, and chalk dusts (erosion and incrustation). Heavy deposits, e.g., of fly ash, on leaf surfaces can impair the photosynthesis efficiency of the assimilation

organs. As well as physical methods of determining the constituents of sedimentary (i.e., deposited) dust and airborne dust, chemical methods are also very important. Dust deposits containing the heavy metals lead, cadmium, and zinc are of particular significance. Zinc is an essential trace element for plants. Plants with an inadequate supply of zinc show deficiency symptoms, but the metal is toxic in excess. Lead and cadmium are not essential for plant life, and have a much greater toxic effect on plant tissue.

These harmful substances enter the plant directly from polluted air, and also indirectly via the roots from soil in which they have accumulated. The main subject of interest is not the slight phytotoxic effects, which are only observed at higher heavy metal concentrations. More important is the fact that plants used for both human and animal food can become contaminated. This contamination can pass down the food chain and endanger the health of humans and animals [109], [110].

3.4.2.9. *Acid Rain*

It had already been established by the mid-1800s that smoke from industrial installations and domestic heating can affect the chemical composition of rain, and that sulfuric acid was one of the pollutants concerned. After 1850, rainwater analyses were carried out in Germany and other countries to determine the effect of air pollution on the penetration of substances into the soil. These investigations were carried out because it was thought that chronic pollution of the soil could also affect plants by this route.

From 1950 onwards, following worldwide discussions on acid rain, regional measurement networks were installed in large parts of Europe and North America [110]. The main measurements made were of the sulfate, nitrate, and chloride levels in the rain, though other substances, e.g., ammonium compounds, were also determined. The highest acid content was found in the industrialized areas of Central Europe, where a pH of 4 was recorded. Rain from areas without anthropogenic pollution had an average pH of 5.6 – 4.6.

Absorption and Plant Reaction. The action of acid rain on plants has mainly been investigated under laboratory conditions. Plants show a considerably greater reaction under laboratory conditions than has been found in the smaller number of open land observations. The absorption of acid rain is influenced by morphological and structural properties of leaves and needles. Under comparable exposure conditions, broad-leaved plants are usually more sensitive than narrow-leaved plants. Damage to the leaf organs takes the form of fossules (pitting), dent-like deformations, and punctiform necroses. The effect of acid rain apparently is to produce more rapid weathering of the cuticle. Chlorophyll degradation is also possible, and the rate of washout of the plant's own nutrients is increased by proton – cation exchange. However, the negative effects of the added hydrogen ions can sometimes be more than compensated for by plant nutrients in the acid rain. The many possible effects of acid rain have been reported in comprehensive studies carried out by VDI [110]. Investigations in the United States have shown that treatment with simulated acid rain led to reductions in the yield of maize and soya beans, these being the most economically important crops in the United States.

Acid rain can cause indirect effects on vegetation via the soil. Changes to the chemical and physical soil condition are particularly important, as borne out by the intensity of the discussion of this complex question. In particular, toxic metal ions that can damage the root system may be liberated. The most important aspect of the action of acid rain on the soil is the increase in the plant availability of toxic aluminum and heavy metal ions due to pH reduction.

A considerable increase in forest damage took place in the 1970s in Germany, and acid rain was immediately thought to be the cause. The first damage was observed to fir trees in so-called pure air regions of Southern Germany. Since 1980, widespread damage to spruce trees has also been recorded. There has also been increasing damage to deciduous trees, in which the symptoms, chronological development, and distribution of the damage were different from those for fir and spruce trees. At first, many different conclusions were drawn by experts on the possible causes of the forest damage. These ranged from the one-sided assumption that the effects were due to exclusively natural factors to the view that they were due only to anthropogenic factors. In the course of the continuing discussion and consideration of the results of new investigations, it appeared more and more probable that forest damage was linked to air pollution whose effects could be changed by natural and/or silvicultural influences. Three possible effect mechanisms are favored [110]:

1. Nutrients are washed out of contaminated soil by acid rain, and toxic metal ions (e.g., aluminum) are released. These damage the plant roots, whose ability to absorb nutrients and water is reduced.
2. The plants are directly damaged in the crown region by acid rain.
3. There is a direct effect of gaseous air pollutants, leading to a certain susceptibility of the whole organism to the subsequent effects of acid rain.

The causes of forest damage are still under discussion. There are other possible factors, e.g., combination effects of various air pollutants, toxic substances as yet unknown, and various stress factors.

4. Laws and Technical Regulations

Gerhard Feldhaus and Klaus Grefen

4.1. Introduction

In Germany, the maintenance of air purity and plant safety have their legal basis in the Federal Antipollution Law or *Bundes-Immissionsschutzgesetz* (BImSchG). This is the most important legislation for the protection of the environment from the point of view of both environmental and industrial politics. It is a demanding law of great importance in environmental politics, aiming to prevent air pollution, to provide protection from noise and vibration, to prevent environmental damage and other hazards, and to promote safety in production plant. Its significance for industrial politics is that almost all industrial and business enterprises require a license before starting operation, and must remain under

continuous environmental supervision by the state during their operation. The BImSchG is therefore effectively a plant licensing law into which extensive environmental protection is integrated.

The law lays down the basic requirements which the plant must satisfy. In doing so, it makes considerable use of so-called undefined legal terms such as harmful effects on the environment, pollution, emissions, hazards, plant, state of the art, precautions, and compatibility. These legal terms are characterized by the fact that their meaning is only partially defined by the law. They therefore admit scope for discretion on the part of the authorities and courts, and thus affect legal security. However, they are unavoidable in law concerning technology in order to be able to keep abreast of scientific and technological developments. “The setting of a given legal safety standard by making rigid rules is more likely to limit both technological development and the preservation of basic rights (if it allows these at all) than to enhance them. It would constitute a backward step at the cost of safety” [decision of the German Federal Constitutional Court (Bundesverfassungsgericht) of Aug. 8th, 1978: the so- called Kalkar Ruling]. The use of undefined legal terms is thus asserted to be fundamentally and constitutionally permittable.

However, undefined legal terms constantly require further definition to give consistent legal applicability. For this, there are several possibilities:

1. Regulations enacted on the basis of BImSchG. The most important of these are those regulations issued by the Federal Authorities for the enforcement of the Federal Antipollution Law (BImSchG). Others are issued by the Länder (e.g., smog regulations). Regulations are legally binding on persons to whom they apply.
2. General administrative regulations. These define the undefined legal terms, with legally binding effect on the executive authorities, or they restrict the discretion of these authorities. The most important of these regulations are the technical instructions for the maintenance of air purity (TA Luft) and protection against noise (TA Lärm).
3. Standards set by groups or committees of nongovernmental technical legal authorities. These can be National Standards (DIN, VDI), EU Standards (CEN, CENELEC), or International Standards (ISO). These standards are only binding if government regulations refer to them. Otherwise, they generally have the status of generalized expert opinion.

Further development in the areas of air pollution prevention and plant safety will be increasingly determined by the following:

1. National legislation will be increasingly controlled by laws made by the EU.
2. In the national, supranational, and international areas, regulations relating to individual environmental pollutants are becoming increasingly incorporated into general antipollution regulations. Examples of the latter include environmental criminal law, the law dealing with tests for environmental compatibility, and the law of liability for environmental matters.

4.2. Federal Antipollution Law

The law relating to the protection of the environment from the harmful effects of air pollutants, noise, vibrations, and similar effects (Bundes-Immissionsschutzgesetz, BImSchG) has been in force since April 1st, 1974. It has been much modified since then, mainly by the 2nd amending law of Oct. 4th, 1985, the 3rd amending law of May 11th, 1990, the law of April 22nd, 1993 relating to capital investment facilitation and residential building land, which has been in force since May 1st, 1993, as well as the law for the acceleration and simplification of antipollution licensing procedures of October 9th, 1996.

The BImSchG brought about a comprehensive legal reorganization of the law on pollution. In particular, it superseded the regulations of the §§ 16 ff. Trade and Industry Code (Gewerbeordnung) and a large number of regulations made by the Länder; included nonlicensable installations; and created new regulations (e.g., for planning, traffic, and products).

The BImSchG makes regulations for the building and operation of installations, but not for effects on the environment that depend simply on human behavior, which are covered by law at the Länder level. As far as air purity and noise reduction are concerned, BImSchG applies to installations in all areas (e.g., industry, trade, crafts, agriculture, and forestry) and includes nationalized and private enterprises (§§ 2). Antipollution Law in the wider sense applies only to profit-making enterprises. It basically does not apply to airports and nuclear power stations.

The law has three aims (§§ 1):

1. The most important aim is protection against harmful effects on the environment.
2. For licensable installations, protection is extended to other hazards such as fire and explosion and risk of disturbances which may be associated with the production of chemical products in particular.
3. The long-term aim is prevention. Even if there are no harmful environmental effects, the aim is to improve the protection of human living space, especially by judicious utilization of modern technology (state of the art).

Pollution prevention law is divided into five main areas:

1. Installation-related pollution prevention
2. Product-related pollution prevention
3. Region-related pollution prevention
4. Traffic-related pollution prevention
5. Organization-related pollution prevention

Installation-related pollution prevention mainly relates to stationary installations, i.e., factory premises. A distinction is made between licensable installations (§§ 4 ff.) and nonlicensable installations (§§ 22 ff.).

Licensable installations are those whose nature or size render them especially likely to bring about harmful effects on the environment or to cause other hazards. They include stationary waste disposal plants in which waste materials are stored or treated. Licensable installations are specified in detail by regulations (4. BImSchV).

Licensable installations may only be erected, operated, or significantly modified if a license has been granted (§§ 4, 15).

Licensable installations incur four fundamental duties (§§ 5):

Duty to Protect. The construction and operation of the installation must not lead to any possibility of harmful effects on the environment or to any other hazards, or to serious detriment or nuisance. This duty extends also to the prevention of pollution. In general the limits of harmful pollutants are more exactly defined mainly in general administrative regulations, especially by the immission values of TA Luft and TA Lärm. These specify at what level of regular exposure there is a harmful effect on the environment. The immission figures are always determined by well-defined measurement and assessment methods. More precise definition is usually provided by nongovernmental regulations, such as DIN standards and VDI guidelines. Duty to protect is more precisely specified for installations where there is a hazard from potential disturbances. Here, methods of preventing such disturbances or of limiting their effects are prescribed in the accident regulations (12. BImSchV).

Duty to Take Precautions. When licensable installations are constructed and operated, precautions must be taken against harmful effects on the environment, in particular by state-of-the-art measures to limit emissions. These are usually assessed by comparison with emission limits as prescribed principally in the TA Luft Regulations, Power Station Emission Regulations (13. BImSchV), and Waste Incineration Plant Regulations (17. BImSchV).

Duty to Avoid, Reuse, or Dispose of Residues. Licensable installations are among the most significant producers of waste. The goal of waste prevention is best served by preventing the generation of residues, or, failing that, by the lawful and nonhazardous utilization of any residues generated. Residues are substances that arise during production and processing that are not desired by the proprietor of the business, who is only absolved from the duty of preventing or reusing these residues if this is technically impossible or unreasonable. The proprietor is then obliged to dispose of the residues as waste materials without impairment of the well-being of the general public.

Duty to Utilize Waste Heat. In 1985, the duty to utilize waste heat produced in an installation was introduced as the fourth fundamental duty. The prerequisite is that such utilization is technically possible and feasible for the type and location of the installation. In 1990, the duty to utilize waste heat was widened to include supplying it to a willing third party. This fundamental duty only applies to installations specified by order of the Federal Government. No such a law has so far been enacted.

The license is always granted by following a formal procedure, i.e., with participation of the public. The procedure is laid down in §§ 10 and 9th BImSchV, and is initiated by a written application to which the documents required for assessment should be attached. These include descriptions of installations and business enterprises, data on emissions, and proposed measures for preventing harmful effects to the environment and other hazards, including a safety analysis in the case of certain installations. The licensing authority receives the statement from the authority whose field of duties is affected by the proposal. If the application documents are completely in order, the proposal is published, and the application and documents must be exhibited for public inspection for one month. Any person then has the right to raise objections to the proposal up to two weeks after the end of this period, i.e., a total of about six weeks. If objections are raised, the licensing authority must discuss these with the objectors and the applicant. In those types of installation specified in column 2 of the Appendix to 4th BImSchV, a simplified license application procedure without the participation of the public is used (§ 19). Discussion is concluded without notification or display of the documents.

In order to speed up the licensing procedure, preliminary decisions can be made for individual licensing prerequisites and for the location of the installation (§ 9). Large installations can be licensed in stages by means of partial licenses (§ 8). With the introduction of the amending law of 1996, modifications to existing plant only require authorization only if they are expected to cause negative effects (§ 16, Section 1). The authorities must be notified of other modifications at least one month prior to implementation (§ 15, Section 1). If an installation is to be significantly altered, the licensing authority, before the required license is granted, can permit commencement of construction of the installation, if at that point in time it can be assumed that a license will be granted, if there is public or private interest in the earlier building of the installation, and the proposer of the project accepts the risk of subsequent refusal of the license (§ 8 a).

If the basic duties of § 5 are fulfilled and the installation satisfies other public legal requirements and concerns of industrial safety the licensing authority must grant the license (§ 6), and the applicant has a legal right in this respect. In accordance with other regulations, the license for the installation includes most of the other licenses (e.g., planning permission) and permits (concentration effect of § 13).

The license authorizes the construction and operation of the proposed installation. Subsequent restrictions to the licensed business are only allowed to a limited extent, especially by subsequent regulations under § 17, but they may not be excessive.

Installations which do not require a license under § 4 are in the category of nonlicensable installations (§§ 22 ff.), e.g., small and medium-sized commercial enterprises, domestic heating, and construction machinery. Less stringent basic duties apply to these (§ 22). For some types of installation, the duties are detailed in official regulations, e.g., 1st BImSchV (small furnaces), 2nd BImSchV (installations that contain halogenated hydrocarbons), 7th BImSchV (wood processing plants).

For both licensable and nonlicensable installations, supervisory procedures may be prescribed, usually according to § 52, or, with special reference to the determination of emissions and pollutants, according to §§ 26 ff. Since Sep. 1st, 1990,

anyone who operates a licensable installation must provide a statement of emissions, and this must be updated every four years (§ 27, 11. BImSchV). In the statement of emissions, figures must be provided for the harmful substances emitted from the installation during the previous calendar year.

Following the 3rd amending law of 1990, BImSchG has been upgraded to the status of a plant safety law. The authorities are empowered to order certain technical safety checks and safety reviews (§ 29 a). The law also provides for the appointment of a technical committee for plant safety (§ 31 a), an accident committee (§ 51 a), and accident representatives (§ 58 a ff.).

Regulations can demand the prevention of harmful effects on the environment from air pollutants, plant noise or vibration, combustible materials, fuels, and other materials and products (§§ 32 ff.). Relevant regulations include: 3rd BImSchV (sulfur content of light heating oil and diesel fuel), and 19th BImSchV (chlorine and bromine compounds used as fuel additives).

A section of the BImSchG is dedicated to the prevention of pollution from traffic. The design and operation of motor vehicles can be regulated in accordance with § 38 with respect to air purity and noise prevention. In still weather, traffic restrictions can be ordered by the Land authorities; the smog regulations issued by the Länder provide the details. Most of the smog regulations so far enacted have since been repealed, since the pollutant load of the air in Germany has been lowered to such an extent by the numerous protective measures that even under smog weather conditions the critical values are no longer attained. However, so-called summer smog — a short-term increase in atmospheric ozone concentrations near the ground under the influence of sunlight — is regarded as a new problem. The amending law of July 19th, 1995 introduced §§ 40 a to 40 e into law. They provide for traffic bans in the event of high ozone concentrations. Since September 1st, 1990, the street traffic authorities can order traffic restrictions, whether in still weather or not, to prevent harmful air pollution, especially in the inner cities (§ 40 Section Physics and Chemistry of the Atmosphere). The twenty-third statutory regulation for the implementation of the Federal Antipollution Law (23. BImSchV) of December 16th, 1996 specifies concentration values for traffic-related air pollution. If these values are exceeded, the responsible authorities of the Länder must determine whether traffic restrictions are necessary, and if so, which measures are to be taken. A complete system of noise prevention for the design of streets, railways, and roads is provided by §§ 41 – 43 in conjunction with § 50. Some details are covered by the Traffic Noise Prevention Order (16. BImSchV).

The prevention of pollution in individual regions is controlled by §§ 44 ff. and § 49. These regulations control regional or local problems of pollution prevention. For areas in which especially hazardous air pollutants occur or are likely to occur, a continuous comprehensive control of air polluting substances is prescribed (§ 44). All significant sources of air pollution are included in an emission register, i.e., industrial and other business enterprises, domestic heating, and motor vehicles (§ 46). The emission register is based on the statements of emissions made in accordance with § 27. If investigations show significantly high concentrations or a continuous increase in air pollution over long periods of time, the setting up of air antipollution plans must be considered for the whole area of investigation or for parts thereof (§ 47). Under certain conditions, the Land authorities must prepare a clean-up plan. In other cases, according to their judgment, they may prepare a precautionary plan. Noise reduction plans may be prepared under certain circumstances in accordance with § 47 a. For areas in special need of protection (highly polluted areas or areas receiving special protection), specially stringent controls may be prescribed (§ 49).

As well as stipulating requirements for environmental technology, the law also lists a number of duties in connection with management structure. Proprietors of businesses that have environmental implications resulting either from emissions or from the products manufactured must appoint an antipollution representative (§ 53). He is the company expert in questions of pollution. His most important task is, on his own initiative, to promote the introduction of environmentally friendly processes and products, and to support the managers of the business therein. Control of the working environment within the company is also entrusted to him (§ 54). He has a special position within the company, having the right to make direct representations to management in important questions. He may not be dismissed as a result of his actions (§§ 56, 57, 58). For especially hazardous installations, the appointment of an accident representative is prescribed (§ 58 a). His rights and duties essentially correspond to those of the antipollution representative (§ 58 b – 58 d). The German Recycling and Waste Act (Kreislaufwirtschafts- und Abfallgesetz) prescribes the appointment of a waste materials representative, also modeled on the antipollution representative, and similarly the water resources policy act prescribes a water pollution representative. These various functions are often assigned to a single member of staff, who then has the function of an environmental representative.

Since Sep. 1st, 1990, proprietors of licensable installations have been obliged to make reports of their management structure to the competent authorities (§ 52 a). In corporations whose authorized representation includes several members, and in unincorporated firms with several legally appointed staff representatives, the authority must be informed who within the management is responsible for pollution prevention. All proprietors of licensable installations must also inform the authority of their method of ensuring that regulations and orders intended to prevent harmful effects on the environment and other hazards will be observed in their organization. In this connection, the management structure must be made known to the authority. The law does not demand a more detailed management structure, but more details emerge, for example, from the stipulations concerning management representatives, accident regulations, and general rules of management structure. Further elements are contained in the EU Regulation of June 29th, 1993 concerning the voluntary participation of business undertakings in a cooperative system for environmental management; investigation of the environmental aspects of a company (ABl. Nr. L 168/1) are regulated by the Environmental Audit Law of December 7th, 1995 and DIN-EN-ISO 14001, 14004, 14010, 14011, and 14012.

4.3. Federal Statutory Antipollution Regulations Relating to Air Pollution and Plant Safety

4.3.1. *First BImSchV*

The first statutory regulation for the implementation of the Federal Antipollution Law (regulation concerning small furnaces – 1. BImSchV) of July 15th, 1988, mainly based on § 23 BImSchG, controls the construction, structure, and operation of furnaces that do not require a license under BImSchG (§ 1), i.e., installations with an output of up to 1 MW

using solid fuel, 5 MW using light heating oil, or 10 MW using gaseous fuel. Small furnaces are important from the point of view of pollution prevention because of their abundance and their relatively high contribution to pollution (low-altitude gas discharge).

Main contents: Limit values for particulates, CO, and oil derivatives (§§ 4 ff.); limitation of NO_x emissions from oil- and gas-fired furnaces by means of state-of-the-art combustion technology (§ 9); limitation of waste-gas emissions for oil- and gas-fired furnaces (§ 11); restriction to certain fuels (§ 3); inspections (§ 14); annual measurements during supervision by the regional stack inspector (§§ 15 ff.); discharge conditions for waste gases (§ 18). Existing furnaces must be modified after a transition period to comply with requirements for new installations (§ 23).

4.3.2. *Second BImSchV*

The second statutory regulation for the implementation of the Federal Antipollution Law (regulation to limit emissions of volatile halogenated hydrocarbons – 2. BImSchV) of Dec. 10th, 1990, based on § 23 BImSchG, applies to nonlicensable installations in which volatile halogenated hydrocarbons are used as solvents, especially surface treatment plants, dry cleaning plants, textile finishing plants, and solvent extraction plants. The regulation incorporates new knowledge about the potential hazards of volatile halogenated hydrocarbons and the ability of volatile chlorofluorocarbons (CFCs) to destroy ozone. This regulation implements The Montreal Protocol of Sep. 17th, 1987 concerning CFCs.

Main contents: The only permitted volatile halogenated hydrocarbons are tetrachloroethyl-ene, trichloroethylene, and dichloromethane, and these may be used only in certain installations (§ 2). Authorization for CFCs expired on Dec. 31st, 1994. Technical requirements, handling methods, and emission limit values are prescribed to limit the emission of permitted solvents. Existing installations must be renovated by Dec. 31st, 1994 at the latest (§ 6). This regulation also contains instructions for measurement and supervision (§§ 10 ff.).

Disposal of solvents from these or similar installations is regulated in the regulations for used solvent disposal (Oct. 23rd, 1989). Other restrictions and prohibitions relating to CFCs are contained in the EU Regulation regarding substances with an ozone-depletion potential of December 15th, 1994. and the CFC – Halon Prohibition Order (May 6th, 1991), which is based on the Chemicals Act.

4.3.3. *Third BImSchV*

The third statutory regulation for the implementation of the Federal Antipollution Law (regulation concerning the sulfur content of light heating oil and diesel fuel – 3. BImSchV) of Jan. 15th, 1975, based on § 34 BImSchG.

Emissions from domestic and small commercial furnaces and diesel vehicles have a major influence on SO_2 emissions in densely populated areas because of their low emission altitude. To reduce these emissions, this regulation limits the sulfur content to 0.20 wt % in light heating oil (following the amending regulation of Dec. 14th, 1987) and in diesel fuel to 0.05 wt % from October 1st, 1996 in accordance with the amending law of September 26th, 1994. The EU Guideline 75/716/EEC of March 30th, 1987 prescribes the lowest possible limit value. Earlier limit values were: May 1st, 1975: 0.55 wt %; May 1st, 1976: 0.50 wt %; Jan. 1st, 1979: 0.30 wt %. Since Oct. 1st, 1996, a new limit value of 0.05 wt % applies for diesel fuel.

4.3.4. *Fourth BImSchV*

The fourth statutory regulation for the implementation of the Federal Antipollution Law (regulation concerning licensable installations – 4. BImSchV) in the version of March 14th, 1997, based on § 4, Section 1, Clause 3, BImSchG specifies the range of licensable installations. Only those types of installations named in the Appendix require a license, usually on the grounds of maintaining air purity. They include almost all industrial installations, e.g., those involving chemicals (see Nos. 4.1 – 4.10). The obligation to be licensed often depends on the capacity or size of an installation and extends to adjacent equipment which is associated with it geographically and operationally and which can have an important bearing on the emission or immission behavior or the safety of the installation, such as the storage of raw materials, finished products, and residues, and equipment for transport, waste materials, packaging, and shipping.

For installations named in Section 1, the license is granted in a formal procedure (§ 10 BImSchG) with participation of the public, and for installations named in Section 2 by a simplified procedure (§ 19 BImSchG), i.e., without participation of the public.

4.3.5. *Seventh BImSchV*

The seventh statutory regulation for the implementation of the Federal Antipollution Law (regulation to limit the emission of wood dust – 7. BImSchV) of Dec. 18th, 1975, based on § 23 BImSchG applies to nonlicensable installations for the working or processing of wood or wood- containing materials if wood dust or shavings are emitted from these installations.

Main contents: Wood dust and shavings must be stored in bunkers, silos, or other closed spaces. These must be emptied in such a manner that the emission of wood dust or shavings is prevented as far as possible (§ 3). Emission limit values are specified for wood dust and shavings. If the exhaust air contains particulates, a limit of 50 mg/m^3 in the exhaust air is imposed (§ 4).

4.3.6. *Eleventh BImSchV*

The eleventh statutory regulation for the implementation of the Federal Antipollution Law (regulation concerning the declaration of emissions – 11. BImSchV) of Dec. 12th, 1991, based on § 27, Section 4 BImSchV, concretizes § 27 BImSchG, which obliges proprietors of all licensable installations to provide a statement of emissions to the competent authority, i.e., information on the type, amount, and distribution over space and time of atmospheric pollutants emitted annually from the installation. The emissions statement is the basis for the emissions register, and for planning and clean-up procedures. Installations with low emissions may be excepted (§ 1). The time period for the statement is the even-

numbered calendar year (§ 3). In general a complete statement of emissions must be supplied, with quantities of these emissions. In certain cases, a simplified statement may be provided, for which operational data and a list of materials handled are sufficient (§ 4). According to § 27, Section 1 of BImSchG in the version of the amendment law of 1996, the emission statement must be updated every four years (formerly every other year). The authority may publish the figures from the emission statement, unless trade and operational secrets can be deduced therefrom (§ 27, Section 3 BImSchG).

4.3.7. *Twelfth BImSchV*

The twelfth statutory regulation for the implementation of the Federal Antipollution Law (accident regulation – 12. BImSchV) of Sep. 20th, 1991, mainly based on § 7 BImSchG, basically applies to all licensable installations in which materials referred to in Appendices II and III or other materials that are highly toxic, toxic, able to support combustion, explosive, combustible, highly flammable, or flammable (Appendix IV) are present or can be formed in an accident. It does not apply if negligible quantities are involved (§ 1). The regulation is intended to prevent accidents and to limit their effects as far as possible. Accidents are disturbances to normal operation in which materials as specified in Appendices II, III or IV lead to a serious hazard from large-scale emissions, fires, or explosions, i.e., danger to life, serious effects on health, or environmental hazards affecting the well-being of the population (§ 2).

Main contents: Basic safety duties (§ 3), detailed safety duties (§§ 4 – 6), safety analysis (§ 7), duty to report accidents and near accidents (§ 11), information to the public (§ 11 a), duty of notification (§ 12). Safety duties requiring qualified personnel (e.g., safety analysis) need only be carried out for installations named in Appendix I (§ 1, Section 2); these are mainly chemical installations.

4.3.8. *Thirteenth BImSchV*

The thirteenth statutory regulation for the implementation of the Federal Antipollution Law (power station emission regulation – 13. BImSchV) of June 22nd, 1983, mainly based on § 7 BImSchG, applies to the construction and design of large furnaces, i.e., installations with a combustion heat output of ≥ 50 MW, or ≥ 100 MW for gaseous fuels (§ 1).

Main contents: Emission limit values for particulates, CO, NO_x, SO_2, and halogen compounds (§§ 3 ff.). A continuous monitoring method is desirable for measurement and assessment (§§ 21 ff.). For NO_x, emission limit values were not finalized, as the technical development was still in a state of flux. Here, so- called dynamic clauses were introduced, requiring the use of the existing state of art. These have since been specified in detail to enable them to be carried out by management. The part with most relevance to air purity consists of instructions for cleaning up old installations (§§ 17 ff.). The regulation gave the proprietors until July 1st, 1984 to decide whether they wished to reequip their installations or shut them down by April 1st, 1993. If they opted for reequipment, this had to be completed by July 1st, 1988. Most furnaces have now been reequipped. Compared with 1980 figures, emissions of SO_2 in 1993 from large furnaces in the “old” Länder of the Federal Republic have been reduced by ca. 80 %, of NO_x by ca. 70 %, and of particulates by ca. 75 %. In the area of power generation, > 11×10^9 € were invested for these measures, of which 7.3×10^9 € were for desulfurization of flue gas and 3.5×10^9 € for reduction of NO_x emissions.

4.3.9. *Seventeenth BImSchV*

The seventeenth statutory regulation for the implementation of the Federal Antipollution Law (regulation concerning incineration plant for combustible waste and similar materials – 17. BImSchV) of Nov. 23rd, 1990, based on § 5 Section 2, and § 7 BImSchG, applies to all licensable installations in which solid or liquid waste or similar solid or liquid combustible materials are burnt, including installations whose main purpose is different (e.g., cement furnaces).

Waste incineration plants are of great significance for the environment because of their emissions of gaseous inorganic chlorine and fluorine compounds, and also because of some constituents of emitted particulates, especially heavy metals and polyhalogenated aromatic compounds. The emission limit values laid down earlier in TA Luft 1986 were made much more stringent, and the requirements of the EU Guidelines of June 1989 with respect to existing and new incineration plants for domestic refuse were incorporated in national law.

Main contents: Emission limit value for dioxins and furans 0.1 ng TEq/m^3 (i.e., reduction in dioxin emissions from waste incineration plants by > 99 %); emission limit values for other air pollutants (§ 5); constructional and operational requirements, e.g., dwell time and minimum temperature (§ 4); and the annual provision of information to the public (§ 18). For existing installations there were a series of intermediate deadlines until March 1st, 1994 or Dec. 1st, 1996 (§ 17).

4.3.10. *Nineteenth BImSchV*

The nineteenth statutory regulation for the implementation of the Federal Antipollution Law (regulation concerning chlorine and bromine compounds – 19. BImSchV) of Jan. 17th, 1992, based on § 34 BImSchG, seeks to reduce pollution of the environment by dioxins and furans by prohibiting the addition of chlorine and bromine compounds (scavengers) to motor vehicle fuel. The marketing of chlorine and bromine compounds as fuel additives and the marketing of fuels that contain such additives is forbidden (§ 2).

4.3.11. *Twentieth BImSchV*

The twentieth statutory regulation for the implementation of the Federal Antipollution Law (regulation to limit hydrocarbon emissions during the transfer and storage of gasoline – 20. BImSchV) of Oct. 7th, 1992, based on § 23 BImSchG and § 24 Trade Regulation.

The object of the 20th BImSchV is to reduce the emission of hydrocarbons during the supply of gasoline. These substances may be directly hazardous to health (e.g., the carcinogen benzene). However, hydrocarbons are also important precursors for the formation of ozone and other photooxidants. The regulation applies to nonlicensable installations to which deliveries of gasoline are made, or from which gasoline is taken, e.g., filling stations, small supply

tanks, and road and rail tankers (§§ 1, 2).

Main contents: In principle, the gas displacement method must be used in filling operations from storage tanks and during deliveries to filling stations. If this is technically infeasible, the gasoline vapors must be passed to a gas- cleaning device (§ 3). The filling of vehicles at filling stations is regulated by 21. BImSchV.

4.3.12. *Twenty-First BImSchV*

The twenty-first statutory regulation for the implementation of the Federal Antipollution Law (regulation to limit hydrocarbon emissions during the filling of motor vehicles – 21. BImSchV) of Oct. 7th, 1992, based on § 23 BImSchG and § 24 Trade Regulation.

The object of 21st BImSchV is to reduce the release of gasoline vapors during the filling of motor vehicles at filling stations. Customers, filling station personnel, and persons who live close to filling stations are exposed to gasoline vapors, which contain the carcinogen benzene.

The regulation applies to nonlicensable filling stations where motor vehicles are filled with gasoline (§ 1). In the filling operation, a gas recycling system must be used which collects the gasoline vapors from the tank of the vehicle and feeds them back to the storage tank of the filling station (§ 3). The regulation applies with immediate effect to new filling stations. Existing filling stations must be equipped with a gas recycling system within not more than five years (§ 9).

4.3.13. *Twenty-Second BImSchV*

The twenty-second statutory regulation for the implementation of the Federal Antipollution Law (regulation concerning levels of pollutants – 22. BImSchV) of Oct. 26th, 1993, based on § 48 BImSchG, incorporates three EU Guidelines into Federal Law: of July 15th, 1980 (80/779/EEC amended by June 21st, 1989 89/427/EEC) on limit values for SO_2 and suspended particulates, of Dec. 3rd, 1982 (82/884/EEC) on the limit value for the lead content of air, and of March 7th, 1985 (85/203/EEC) on air quality standards for NO_x. The regulation became necessary after the European Court of Justice in May 30th, 1991 judged that the Federal Republic of Germany had not duly incorporated these guidelines. The limit values named in the guidelines are established as pollution limit values by the regulation (§ 1). The following were also established: the main reference time periods (§ 2), criteria for the location of measuring points (§ 3), and the methods of measurement and analysis (§ 4). The actions necessary if the limit values are exceeded are specified in § 6 (air purification plans, official orders). TA Luft is unaffected according to § 5.

4.3.14. *Twenty-Third BImSchV*

The twenty-third statutory regulation for the implementation of the Federal Antipollution Law (regulation concerning the stipulation of concentration values – 23. BImSchV) of December 16th, 1996 specifies, for certain streets or areas in which especially high traffic-related pollution levels are to be expected, concentration values for nitrogen dioxide, soot, and benzene. If these values are exceeded, the need for traffic-restricting measures must be determined.

4.3.15. *Twenty-Fifth BImSchV*

The twenty-fifth statutory regulation for the implementation of the Federal Antipollution Law (regulation to limit emissions from the titanium dioxide industry – 25. BImSchV) of November 8th, 1996, based on § 48 a, Section 1, Clause 1, BImSchV, applies to the production of titanium dioxide, the concentration of weak acid, and the cleavage of sulfate-containing salts. It specifies values for dust, sulfur dioxide, sulfur trioxide, and chlorine (§ 3, 4).

4.3.16. *Twenty-Seventh BImSchV*

The twenty-seventh statutory regulation for the implementation of the Federal Antipollution Law (regulation concerning crematoriums – 27. BImSchV) of March 19th, 1997 is based on §§ 4 and 19, BImSchG. The regulation applies to crematoriums and contains requirements regarding the use of fuels, technical requirements, emission limits (§§ 3, 4), and measurement specifications (§§ 7 – 10).

4.3.17. *Other Federal Regulations*

The Law on Testing for Environmental Compatibility of Feb. 12th, 1990 is based on the EU Guideline of June 27th, 1985 on testing for environmental compatibility for certain public and private projects (85/337/EEC).

Testing for environmental compatibility must be carried out for the most important licensable installations, nuclear installations, projects involving water, mining installations, trade installations, and other installations (Appendix to § 3 of the law).

The proposer of the project determines and describes the foreseeable effects of the project on the population and the environment. This involves a process of communication and consultation with the relevant authorities and the general public. The competent authority then presents and appraises all the information on the project in a comprehensive report. The findings concerning licensing of the project are considered using the prescribed official procedure, and must be made available to the public. For licensable installations, the test for environmental compatibility is carried out as part of the licensing procedure. Details of this are given in 9th BImSchV.

The Law of Liability for the Environment of Dec. 10th, 1990 establishes liability for damage to the environment caused by installations specified in Appendix I (§ 1). These include the most important (according to the BImSchG) licensable installations. Liability is not limited to accidents or disturbances, but also includes normal operation (§ 5, § 6 Section 2). Liability is considerably increased by the presumption of cause in § 6, i.e., if an installation is liable to cause the damage produced, it is presumed that the damage was in fact caused by the installation. The authorities can set aside the presumption of cause on receipt of proof that the installation was operated in accordance with regulations.

Environmental Sanctions. According to the 18th Criminal Law amendment (law for combating environmental crime) of March 28th, 1980, modified as of June 27th, 1994 a special section on criminal offences against the environment was introduced into the penal code. The penal code of §§ 324 – 330 d includes the following punishable offences: § 325 (air pollutants hazardous due to the improper operation of installations), § 327 (illicit operation of installations), § 329 (imperilment by air pollutants of areas needing protection), § 330 (serious hazard to the environment), § 330 a (serious hazard due to the release of toxic substances).

4.3.18. *Smog Regulations of the Länder*

By the powers given to them in §§ 49 Section 2 and 40 Section 1 of the BImSchG, the individual Länder (with the exception of Mecklenburg-Vorpommern) have issued smog regulations which control the designation of smog zones, and specify measures to be taken to restrict traffic and reduce emissions in the case of a smog alert. The hazard levels (warning, first-stage alert, second-stage alert) correspond with the following measures:

1. Temporary restriction of the operation of plant (including complete shutdown)
2. Restriction of the use of certain fuels (e.g., high-sulfur coals and heating oils) in industrial and business enterprises and communal and private households
3. Prohibition of traffic for certain periods, certain vehicles, and certain zones

The smog regulations of the Länder follow the so- called model regulation developed by the Länder antipollution commission and therefore have essentially the same structure, although each Land has its own special features. All smog regulations, as well as defining and prescribing the above warning stages, contain certain smog event criteria. These criteria are based on both the actual meteorological conditions and the air pollution situation. Whereas the definition of still weather conditions can differ from Land to Land (e.g., for North Rhine Westphalia the definition is an average wind speed of < 1.5 m/s at ground level over a period of 12 h, but for Bremen 4 m/s), in all smog regulations of the Länder uniform criteria apply to the decision as to when a given concentration of harmful substances corresponds to one of the alert stages. However, the number and distribution of the measuring stations in the network of pollution monitoring stations in the smog zones of the Länder are different, so that ultimately the methods of deciding on the various alert stages in the individual Länder also differ. For example, different rules apply to the issuing of a smog alert if the concentration figures found exceed the limit values (for SO_2 in combination with suspended particulates, for SO_2 alone, for NO_2, or for CO) at more than 50 % of the measuring stations, at all measuring stations, or at, e.g., two neighboring measuring stations.

A smog alert is issued if the concentration limit values for only one of the above-mentioned harmful substances or for SO_2 in combination with suspended particulates are exceeded (e.g., the 24-h average and the last 3-h average of the sum of the concentration of the SO_2 and twice the concentration of suspended particles, or if the 3-h average for SO_2, NO_2, or CO is exceeded).

4.4. General Administrative Regulations for the Prevention of Air Pollution

The Federal Government is empowered according to § 48 BImSchG, after hearing the parties concerned and with the approval of the Bundesrat, to issue general administrative regulations. These regulations, which in principle are binding on the administrative authority only, serve to implement BImSchG and the statutory regulations made under this law.

4.4.1. *TA Luft*

The first general administrative regulation (Allgemeine Verwaltungsvorschrift – 1. AVwV) of the Federal Antipollution Law (Technical Directions for the Prevention of Air Pollution, or Technische Anleitung zur Reinhaltung der Luft, TA Luft) is an important instrument for the implementation of the Federal Antipollution Law. As described in Part 1 of the four-part TA Luft, this is to be applied in particular

1. When considering applications for a license for the construction and operation of an industrial installation, for any significant change in its location, design, or operation, or for a cleanup of such an installation
2. When considering applications for a preliminary decision
3. For supplementary regulations
4. When ordering the determination of the nature and extent of the emissions from an installation and of the extent of pollution in the zone of influence of the installation

The first TA Luft regulation, issued in 1964, has since been amended several times. The chronological development was as follows:

Sep. 8th, 1964	General administrative regulation for licensable installations according to §§ 16 industrial code (TA Luft 64).
Aug. 28th, 1974	First general administrative regulation (TA Luft 74) of the BImSchG. This was brought into operation in March 15th, 1974.
March 4th, 1983	Amendment of TA Luft. This was largely restricted to a revision of the regulations for licensing procedures and for the assessment of pollution for “defense against hazards”.
March 1st, 1986	Amendment of TA Luft following amendment of the BImSchG (Oct. 4th, 1985) and the earlier (July 24th, 1985) amendment of 4th BImSchV for licensable installations, with adjustment of the installation catalog to conform to technical developments. The “principle of prevention” was increasingly taken into account, and the cleanup concept for old installations was first established.

The four parts of TA Luft are as follows:

1. Scope
2. General instructions for the prevention of air pollution
3. Requirements for the limitation and determination of emissions
4. Requirements for old installations (cleanup)

Part 2 of TA Luft (see above for further details of Part 1) specifies in more detail the mainly undefined legal terms included in the expression “harmful effects on the environment due to atmospheric pollution”. Explanations are given of, e.g., the assessment of health hazards, significant detriment, significant pollution, assessment in those cases where limit values have not been established, and abnormal occurrences. In No. 2.5, in explanation of § 5 of 1 BImSchG, the term “harmful effects on the environment” is defined for important pollutants by means of limit values. A distinction is made between pollution levels at which there are health hazards and levels at which significant detriment and pollution occur. In the latter case, an abnormal occurrence investigation (No. 2.2.1.3 TA Luft) is required if a pollution limit value is exceeded, and this must also be carried out for substances for which no pollution limit values are specified in TA Luft but where there is “reasonable suspicion of harmful effects on the environment”. Other fundamental explanations in Part 2 of TA Luft concern, e.g., the term “precautions”, and give information about methods of limiting carcinogenic substances, the consideration of applications for the granting of an interim action, a partial license, modifications to a license, and the discharge of waste gases. In No. 2.6, “determination of pollution parameters”, important aspects of pollution measurement (measurement planning, sampling, and analysis) are described, and guidelines can be obtained from the VDI handbook of air purity prepared by the KRdL (Kommission Reinhaltung der Luft, or Commission for the Prevention of Air Pollution) formed by the VDI (Verein Deutscher Ingenieure, or Association of German Engineers) and DIN.

In Part 3 “limitation and determination of emissions”, emission limit values corresponding to state-of-the-art technology for licensable installations are specified, and emission minimization requirements are laid down. Large furnaces are not included, as these are covered by 13th BImSchV. Methods for the measurement and control of emissions are specified in Part 3. Emission measurement techniques are described in more detail in the VDI Guidelines listed in Appendix G. Finally, No. 3.1.1 of TA Luft refers to continuing detailing of the state of the technology as defined by the BImSchG, and to the guidelines for process and gas cleaning in the VDI handbook on the prevention of air pollution. These are listed in Appendix F.

A comprehensive plan for cleaning up old installations is set up in TA Luft 86, Part 4. Old installations must be renovated within a given time limit (between “immediately” and 10 years), depending on the type, quantity, and hazardous nature of the emissions and on any special features of the installation. A distinction is made between “supplementary regulations” with immediate effect for the prevention of harmful effects on the environment under certain conditions (if pollution limit values are exceeded or carcinogenic substances are emitted) and precautionary supplementary regulations. As for new installations, the severity of the precautionary requirements (time limits, technical measures) depends on the potential hazard of the emitted substance. Measures to minimize emissions are in all cases fundamentally preferable to improving the condition of discharges.

Unlike laws and regulations, TA Luft is an instruction to the authorities, and does not directly affect individual citizens. However, as its provisions affect antipollution licensing procedures, they have an indirect effect on individual citizens or proprietors of installations with respect to the principle of equality. TA Luft sets measuring standards that are uniform nationally and therefore ensure uniform treatment of proprietors and uniform legal security. Any deviation from its provisions is possible only in exceptional circumstances, e.g., if these provisions no longer correspond to a technological development.

4.4.2. *Fourth BImSchVwV: Determination of Air Pollution in Test Areas*

The general administrative regulation (AVwV) of Oct. 26th, 1993 is based on § 44 Section 1 BImSchG and certain guidelines by the European Parliament. It contains definitions of terms and instructions on the object of measurement, measurement areas (test areas as defined by § 44 Section 3 BImSchG), number and position of measuring points, measuring methods, measuring equipment, and the assessment of results. In order to inform the public about the pollution situation, the data must be provided in a prescribed form suitable for publication. In Appendices A – E of this AVwV, directions are given on EU Guidelines to be considered, the choice of measuring points and instructions to be followed, and the DIN Standards and VDI Guidelines that provide measuring techniques and the determination of process parameters (see also Section TA Luft). The data must be recorded in a standard form, i.e., following the pattern given in Appendix E, and must be transmitted in the form of a report to the EU Commission. Furthermore, the data must be transferred to the German Parliament in accordance with § 61 BImSchG and, in accordance with the highest Land Authorities, to the Federal Environment Office.

The EU (or EEC) Guidelines cited in Appendix C1 and the corresponding Federal Guidelines mentioned in C2 for the monitoring of pollution are of special importance:

1. Guidelines for the construction and testing of the suitability of measuring equipment for the continuous monitoring of pollution (Gemeinsames Ministerialblatt (GMBl), 1981, p. 355)
2. Guidelines for selecting the location and method of construction of automatic measuring stations in telemetric measurement networks (GMBl, 1983, p. 78)
3. Guidelines for establishing reference methods, choosing methods of measuring equivalence, and using calibration procedures (GMBl, 1988, p. 191)

The AVwV will make it possible to establish a uniform federal practice and increasingly a European practice in the determination and monitoring of pollution for the assessment and improvement of the state of air pollution prevention.

4.4.3. *Fifth BImSchVwV: Register of Emissions in Test Areas*

The 5th BImSchVwV of April 24th, 1992 (amended on March 24th, 1993) contains legal requirements which the competent authorities must take into account regarding the establishment and regular updating of emission registers. These registers must be established for the test areas created in accordance with § 44 Section 3 of the BImSchG, in particular for the preparation of air antipollution plans (§ 47 BImSchG). Groups of emitters particularly affected include licensable furnaces (as specified in 1. BImSchV), and other furnaces. This AVwV also applies to “other non-licensable installations” with emissions of volatile halogenated hydrocarbons (as specified in 2. BImSchV) and wood dust (as specified in 7. BImSchV).

They also apply to nonlicensable installations where organic solvents are used if 2nd BImSchV does not apply, e.g., plants for recycling residues, painting, printing, smoke- curing or fumigation, also roasting plants, filling stations, stationary internal combustion engines, surface-treatment plants, and chemical cleaning plants. Other groups to be considered as emitters include livestock, installations of the Federal Railroads, Federal Postal Administration, and Federal Armed Forces, road vehicles, railroad locomotives, shipping, aircraft, and agricultural and military traffic “if inclusion of the emissions is necessary for preparation of the emission register”.

The following substances or groups of substances produced by the emitters listed above are to be considered: dust, lead and inorganic lead compounds, sulfur dioxide, nitrogen oxides (expressed as NO_2), carbon monoxide, and 11 other substances or groups of substances including asbestos, diesel exhaust particles, ammonia, and especially those substances specified in No. 2.3 of TA Luft (carcinogenic substances).

The measurements are carried out either continuously or as individual measurements.

The setting up and presentation of the emissions register (style and scope) is carried out in accordance with established principles to make the data consistent and readily assessible, and to enable and facilitate the updating of the emission register. Thus, the style, scope, and system of presentation are regulated for the individual groups of emitters. The conclusions of the emissions statement order are also important here. The use of 5th BImSchVwV should provide the authorities and other participants with effective instruments for developing measures for reducing emissions and for calculating the spread of pollution.

4.5. Technical Regulations for the Prevention of Air Pollution

The term “technical rules” includes not only technical rules (TR) referred to explicitly under that name, but also standards, guidelines, directions, instructions, worksheets, leaflets, and recommendations produced by various private institutions. However, a technical rule in the wider sense is not only to be regarded as the responsibility of the private maker of rules, but can also require Governmental regulation (e.g., TA Luft). In this section, the issuing of technical rules for the prevention of air pollution by the private institutions DIN, VDI, CEN (Comité Européen de Normalisation), and ISO is described in more detail in the national, European, and international context. These private institutions make an important contribution to the prevention of pollution within the State by converting so- called anticipated expert reports into the format of technical rules. All areas of technology except electrical technology are included. In the DIN catalog of technical rules in the DITR (Deutsches Informationszentrum für Technische Regeln, or German Information Center for Technical Rules), more than 130 private organizations are listed as rule makers. Over 200 regulatory handbooks are recorded. In 1998, ca. 230 000 documents were entered as “technical rules” in the DITR databank in Berlin. Every year, ca. 6000 technical rules are added, and ca. 3000 are withdrawn and hence invalid. The DITR also operates and makes available the multinational and multilingual standards databank PERINORM. This contains the bibliographical information for all valid national standards and proposed standards for Germany, the United Kingdom, France, Austria, Switzerland, and The Netherlands, all European and International Standards, all other valid technical rules in Germany and France, and information on technical rules originating from Government and other authorities, including EU Guidelines. In total, PERINORM 1998 contains over 236 000 entries. PERINORM data can be obtained directly from the DITR, or by using the computer disks available from DITR. The DITR is thus an important instrument for providing reviews and information on technical rules, including those relevant to environment protection.

4.5.1. *National Regulations*

In mid-1990 in Germany, the then existing organizations (the VDI Commission for the Prevention of Air Pollution and the DIN Standards Committee for the Prevention of Air Pollution) merged to form the *Kommission Reinhaltung der Luft (KRdL) im VDI und DIN Normenausschuß* (Commission for the Prevention of Air Pollution in the VDI and DIN Standards Committee). The task of this committee is the preparation of VDI Guidelines, DIN Standards, DIN Provisional Standards, DIN – EN Standards, and DIN – ISO Standards. The office of the KRdL took over the secretariat of the ISO/TC (Technical Committee) 146 “Air Quality” (see also Section International Regulations.) of the DIN Standards Committee for the Prevention of Air Pollution. Furthermore, on the initiative of the KRdL, the CEN/TC 264 “Air Quality” was established in March 1991 (see Section European Regulations.). The secretariat of the KRdL is also responsible for this technical committee. In the establishment of technical rules for the prevention of air pollution, the principles, rules of procedure, and priorities of the DIN (in accordance with DIN 820) and also those of CEN and ISO apply to the procedural guidelines created for the KRdL. In the preparation of VDI Guidelines, the procedural guidelines of the VDI (in accordance with VDI 1000) must be followed.

The KRdL comprises over 200 working groups made up of ca. 1700 specialists in economics, science, and administration working together in an honorary capacity. The KRdL is subdivided into several specialist groups:

Group I. environmental protection techniques
Group II. environmental meteorology
Group III. environmental quality
Group IV. environmental measurement techniques

The work of the KRdL is supported financially by the Federal Government, whose interest in the work of the Commission is

apparent from the statement of the case for the budget, according to which “the Federal Ministry for Environment, Nature Conservation and Nuclear Safety is supported by the KRdL in the performance of tasks in the area of prevention of air pollution as defined by § 1 of the Federal Antipollution Law such that the KRdL, in voluntary self-responsibility and together with the participating authorities, science, and industry, determines the current state of the art in science and technology and records this in guidelines and standards whose contents can become part of the function of the executive and the legislature”.

The KRdL is in charge of ca. 500 VDI Guidelines and DIN Standards, which form the six-volume VDI/DIN Handbook “Prevention of Air Pollution”. The actualization and upkeep of and assistance with ca. 40 DIN/ISO Standards also fall within its sphere of responsibility. The first European Standards (EN) for the prevention of air pollution are in preparation.

4.5.2. *European Regulations*

The protection of the environment is becoming more and more a political topic of the European Union (EU). The 5th Antipollution Action Program of the EU came into force on Jan. 1st, 1993, and will continue until the year 2000. The EU is politically active in the area of technical regulations. In its resolution (85/C 136–01) of May 7th, 1985, which refers to a “New Concept” in the field of technical harmonization and standardization, the European Parliament resolved to limit the harmonization of official regulations of the EU to basic necessities, and commissioned the existing private legislative bodies CEN (Comité Européen de Normalisation) and CENELEC (Comité Européen de Normalisation Electrotechnique) with the preparation of European Standards (EN) for the regulation of technical/scientific matters taking into account the current state of the art of science and technology. The European Standards Committee, CEN, includes the national standards organizations of the 18 countries of the EU and EFTA and the Czech Republic.

DIN officially represents the Federal Republic of Germany as a member of CEN (office in Brussels). A European Standard (EN) is developed with general consent, and is adopted by qualified majority vote. It must then, irrespective of the way in which the individual member country has voted, be included unchanged in all national standards, and becomes a DIN – EN Standard in the Federal Republic of Germany. National standards that conflict with it must be withdrawn in all CEN member countries. During the development phase of an EN under the umbrella of CEN, the so- called Standstill Agreement applies to the national standards may be written or published on the subject of this EN.

To avoid trade restrictions that could arise through national technical rules, CEN, in cooperation with EU and EFTA, provides an information service for standardization work carried out in the European countries (Guideline 83/EEC – Information Service on Standards and Technical Regulations, updated in 1998). This openness about national standardization plans enables possible conflicts between member countries to be largely avoided, and allows coordinated standardization programs to be set up. Moreover, following an agreement on cooperation made in 1984 between the EU, EFTA, and CEN/CENELEC, the European Standardization Committees of the EU and EFTA are mandated to carry out special standardization work. In applying the above mentioned “New Concept” to the field of technical harmonization and standardization, the results of this standardization work form the necessary supplementation for the completion of the EU Guidelines and their incorporation in national law. The European standardization work on air quality is an important example of this.

In March 1990, the Commission for the Prevention of Air Pollution (KRdL) in VDI and DIN proposed to CEN a technical committee “Air Quality”. In October 1990, this application was approved by the CEN member organizations. The office of the KRdL was empowered to take over the tasks of the secretariat. The inaugural meeting of CEN/TC 264 “Air Quality” took place in March 1991 in Bonn.

The scope of CEN/TC 264 “Air Quality” was defined at the inaugural meeting in Bonn as follows: “Standardization of methods for the characterization of air quality with respect to emissions, pollution, air within buildings, gases in the soil and emitted by it, and waste dumping, especially:

- the establishment of uniform measuring procedures for air pollutants (e.g., particles, gases, odors, and microorganisms) and methods for determining the effectiveness of systems for cleaning waste gas, but excluding:
- the establishment of limit values for pollutants
- work areas and clean rooms
- radioactive substances.”

The subject of “air within buildings” is expressly mentioned in the definition of the scope of CEN/TC 264. This topic will become even more important in connection with the EC building materials guideline. The EU Guideline on the incineration of hazardous waste is of special relevance to the European standardization work for the prevention of air pollution. The object of this EU Guideline is “to preserve the environment and improve its quality, and to contribute to the protection of human health”. In contrast to the former EC Guidelines on domestic waste, this EU Guideline sets stringent requirements which must be adhered to by all EU Member States. These stringent requirements prescribe specific techniques of both pollution limitation and measurement to achieve the low limit values. The guideline thus sets new standards in the field of EU Regulations for the prevention of air pollution.

Technical details of measurement are not discussed in the guideline itself. Instead, for information on measurement techniques, reference is made to European Standards (EN), or, if these are not available, to ISO Standards.

The measurement techniques used in existing national standards were often designed for considerably higher emission concentrations than those to be expected when European pollution reaches the low levels predicted for the future in the above EU guideline. There is therefore a need to review procedural parameters or even to develop completely new reference methods. Thus the CEN/TC 264 Technical Committee is required in many cases to provide improvements to measurement techniques or to carry out comparative testing of existing methods. For this, the standardization work for verification of procedural parameters will be accompanied by extensive European measurement programs (interlaboratory

testing). For example, in association with the standardization work, elaborate comparative tests of various methods of measuring dioxin levels at domestic waste incinerators in Germany and Austria have been carried out. Six institutes from EU and EFTA countries contributed to these investigations. The measuring methods for threshold/guideline value monitoring of 0.1 ng/I-TEq m^3 for the dioxins or 10 mg/m^3 for HCl (24-h average 5 mg/m^3) must be validated. These two projects were mandated and financially supported by the EU (100 % support for the measurements, 50 % support for preparing the standards). This financial support ensured that the work was carried out in the time set by the EU (1996).

4.5.3. *International Regulations*

The ISO (International Organization for Standardization), founded in 1947 and based in Geneva is a worldwide association of national standards organizations. Only one national standards organization of any country can be a member of ISO at any one time. Over 70 % of the national member organizations of the ISO are linked with the government, or become so linked by incorporation into the law of the member country. The national member of ISO for Germany is DIN. The results of the work of ISO are published as International Standards (ISO Standards). Standardization for electrical technology is covered by the IEC (International Electrotechnical Commission).

The work of ISO worldwide is carried out by ca. 20 000 experts in over 200 technical committees (TCs). Each TC has a secretariat which is based at one of the national member organizations. Important environmental protection secretariats of ISO are assigned to DIN.

Up to 1998, ca. 11 000 ISO Standards have been published. An ISO Standard is the result of the cooperative work of experts in the individual national member organizations, and is carried out according to fixed rules. It can be valid both as an ISO Standard in its own right and after conversion into a national standard (e.g., a DIN – ISO Standard).

Every year, ca. 10 000 working documents worldwide are sent for further processing in the national working committees for agreement and to obtain the national votes. Meetings in the international area are called as necessary. ISO Standards are reviewed every five years for their validity or in case of scientific or technological developments. The ISO/TC 146 “Air Quality” was established in 1971. The secretariat was taken over by the office of the Standards Committee for the Prevention of Air Pollution (N Luft) of DIN. As the “KRdL of the VDI and DIN” was formed in 1990 (see Section National Regulations), the office of the KRdL in the VDI and DIN in Düsseldorf took over the secretariat of the ISO/TC 146.

The scope of the ISO/TC 146 “Air Quality” is as follows: “Standardization in the area of air quality including definition of terms, air sampling, measurement techniques, and reporting of characteristic values for air. Limit values for air quality are excluded.” The ISO/TC 146 comprises ca. 40 working groups from which four subcommittees (SCs) are formed. The meeting of the ISO/TC 146 in the autumn of 1993 in Philadelphia set up two new subcommittees for “Indoor Air” and “Meteorology.”

To prevent trade restrictions in third party countries, close cooperation and the performance of standardization work by harmonization of the standardization programs of CEN and ISO are extremely important. The cooperative work between ISO and CEN is therefore regulated by the Vienna Agreement of July 1991. Also, the cooperative work of the national standardization organizations with CEN and of CEN with EU/EFTA is carried out according to fixed rules and on the basis of formal agreements. New European standardization projects can be proposed by any CEN/CENELEC member, by any European organization, and by the Commission of the European Union.

5. Air Pollution Monitoring

Peter Bruckmann and Hans-Ulrich Pfeffer

Air pollution monitoring is the systematic measurement of impurities in the atmosphere at locations where harmful and/or adverse effects on “acceptors” such as humans, animals, plants, or materials may occur (immission measurements). Atmospheric impurities are trace substances that are not natural components of the atmosphere [128] or substances whose concentration in the atmosphere deviates significantly from the natural level as a result of human activities [129].

Assessment is made by comparing measured levels of substances (e.g., concentrations, m/V; amounts deposited $m\,A^{-1}\,t^{-1}$, or doses, m (harmful substance/m (body weight) × t or $m\,V^{-1}\,t^{-1}$) with limit values based on their effects. These limit values are specified to protect acceptors from harmful environmental effects and to maintain natural living conditions [130], [131], [132], [133-137].

However, attempts to provide the fullest possible monitoring of air pollution in a given area encounter the following main difficulties:

1. In densely populated and industrial areas, the number of hazardous substances that can be emitted into the atmosphere and are listed in the emissions registers can run into hundreds. These substances have very different chemical, physical, and toxicological properties, and their concentrations can extend over 12 orders of magnitude (from mg/m^3 to fg/m^3). This precludes any simple, quick measurement and assessment.
2. The dynamics of the atmosphere and the variation in the emissions over space and time lead to large variations in the concentration of atmospheric impurities over space and time. The measurement of all possible air quality conditions in an area (statistically, the “population”) is not practicable, so that measurements of pollution always have the character of spot checks.

The above difficulties have led to the development of a wide range of specific measuring techniques and make detailed measurement planning necessary.

In this chapter, both measuring methods and measurement planning are described for the most important fields of air pollution monitoring. Related topics such as the monitoring of air in buildings and the measurement of ground air are not discussed. Reviews can be found in [138], [139].

5.1. Measurement Planning

5.1.1. *Types of Air Pollution Monitoring*

The starting point of every measurement plan is the precise definition of the questions to be addressed by the results. Examples of important pollution measurement tasks are:

a. General air pollution monitoring [132], [133], [137] for the assessment of effects on public health and/or the environment and for compliance checking
b. Measurements for the authorization of industrial facilities [140]
c. Real-time measurements of acute episodes of high atmospheric pollution (winter smog [133], high ozone concentrations [135])
d. Orientational (screening) measurements [141], [142]
e. Measurements following complaints around industrial plants
f. Source identification and source apportionment [143], [144]
g. Measurements in cases of fire and accidents [145]
h. Measurements for research purposes

Each of these tasks requires its own dedicated measurement plan.

The most important area of activity is the assessment of air quality in given areas for compliance checking. This applies in particular to countries that have imposed limit values on pollution levels [130], [133-135]. In their antipollution policies, these countries usually employ the dual strategy of imposing limits on both emissions and levels of environmental pollution. Limit values for air quality are intended to reduce both harmful effects on the environment and hazards to health (smog), and can also have preventive effects [132]. If these limit values are exceeded, emission reduction must follow. They are therefore an element of pollution control.

5.1.2. *Planning of Pollution Measurements*

The measurement of environmental pollution should be planned in such a way that the results will answer at minimum costs all the questions they are designed to meet with given requirements for the uncertainty (accuracy) [146], [153], [133], [154] and representativeness of the data. The measurement plan therefore includes an assessment of technical, financial, and personal aspects. The important parameters that must be fixed in any measurement plan are listed in Table 6 [147].

Table 6. Parameters of pollution measurements to be established for a measurement plan [147]

Parameter	Topics which have to be addressed
Problem analysis	questions to be answered by the measurements, background information, available data, required uncertainty, pollutants to be assessed
Organization	project leader, qualification of personnel, time schedule, available budget
Measurement methods	requirement of standardized methods, performance characteristics (e.g., detection limit, temporal resolution), documentation and data processing, costs
Measurement strategy	measurement area; spatial and temporal resolution, sampling periods and measuring times; sites of the measurements; sampling height
Data evaluation and reports	algorithms to calculate characteristic values, treatment of values below the detection limit and of data gaps, treatment of outliers, structure of report(s)
Quality assurance	quality assurance measures, also for subcontractors; determination of measurement uncertainty

5.1.2.1. *Measurement Networks (General Air Pollution Monitoring)*

The requirements of the European directives [132], [133-137] as one outstanding example for general air pollution monitoring can be summarized as follows:

- Air quality must be assessed over the whole territory of a Member State.
- Air quality for the protection of human health shall be monitored:
  - in areas which are representative for the exposure of the general population (urban background)
  - in areas where the highest concentrations occur to which the population may be exposed for a significant period (hot-spot locations)
- Air quality for the protection of ecosystems shall be monitored with a spatial resolution of at least 1000 km^2.

Bearing in mind the large variation of atmospheric pollutants over space and time and the great number of possible hot-spot locations (busy streets, surroundings of industrial facilities), it is apparent that these ambitious requirements cannot be achieved by measurements alone. A combination of continuous measurements with other assessment techniques such as diffusion modeling, indicative spot-check measurements, analysis of emission inventories, and intelligent data

interpolation is called for, to get at least an approximation of the real air quality. Guidance has been published for the design of monitoring networks [156] and for the assessment of air quality [157].

The recommended approach uses a stratification of measurement locations. The population of possible measurement locations within the area to be investigated is divided into strata of elements with common characteristics [155]. Typical strata of measurement locations, or microenvironments, are urban background areas, sites exposed to traffic, rural areas, and industrial sites. One or more measurement stations are then placed at those locations which are representative for the pollution burden of these typical microenvironments. The monitoring results of these stations can, at least in principle, be transferred to similar locations of the same microenvironment.

This exposure-related approach is also often used in health-related monitoring studies [158]. Information on the position and extent of the microenvironments can be obtained from the analysis of emission inventories, geographical information (location of busy streets combined with traffic density and adjacent built-up areas), and diffusion modeling.

One of the problems this approach must cope with is the widely differing spatial structure of the air pollution, which makes different spatial resolutions of the assessment necessary. Whereas air quality in rural areas is quite homogeneous (a spatial resolution of several hundred or thousand square kilometers is sufficient), pollution levels within a busy street canyon and in a backyard only 50 m apart can differ by up to a factor of two. Consequently, the necessary spatial resolution of the assessment comes down to several hundred square meters. Urban background locations in typical residential areas are in between, with necessary spatial resolutions of several square kilometers. Also industrial sources with fugitive emissions such as cokeries or steel mills [144] can have a high spatial gradient of their air pollution, and a spatial resolution of 250 × 250 m^2 is recommended for assessment [136], [157].

The measurement uncertainty caused by the dynamics of the atmosphere and the emissions can be reduced to the uncertainty of the spatial distribution by using continuous monitors (see Automatic Measuring Methods). In addition, continuous monitors for SO_2, NO_2, or ozone can be used to survey smog-alert thresholds [133], [135]. However, for pollutants such as most organic species, heavy-metal compounds, or other contents of suspended particulate matter, discontinuous sampling with subsequent analysis in the laboratory must be applied. Consequently, in addition to the uncertainty caused by the spatial variability of air pollution, a second part of the uncertainty budget caused by insufficient time coverage of the spot-check sampling comes into play. Statistical methods have been developed to estimate this uncertainty and to determine the necessary number of measurements to obtain a given uncertainty [159], [160].

The results of diffusion modeling, particularly in the case of busy streets, and of indicative measurements with comparably cheap equipment such as passive sampling [161], [142], [162], can be used to find locations for monitoring stations which are representative for the microenvironment in question.

To safeguard a comparable monitoring approach in Europe, the directives [133-136] require a minimum number of fixed sampling sites, which depend on the pollution burden (monitoring efforts must be higher near or above the limit values than at low pollution levels). In addition, the number of costly monitoring stations can be reduced if additional assessment tools such as diffusion modeling or an analysis of emission inventories have been applied.

The ultimate aims of this approach are pollution maps. However, the uncertainty of this spatial representation of the pollution burden will depend inter alia on two factors:

- How complete have hot-spot locations been detected and taken into account?
- How uncertain is the transfer of typical monitoring results within a microenvironment to other locations of the same type of microenvironment?

Bearing in mind the limited amount of technical and human resources available for general air pollution monitoring, it is evident that a good approximation of the air pollution over a given area is all that can be hoped for. Statistical methods [148], were developed to assess the standard error expected when figures determined at the measurement points are used to estimate corresponding figures at points in the surrounding area.

An alternative approach to designing monitoring networks starts with the aim of describing the pollution burden in a given area as representatively as possible, irrespective of the location of specific microenvironments or goods to be protected. The principal idea of this approach is to arrange the measurement sites in a regular grid, e.g. 1 × 1 or 4 × 4 km. If this regular structure of the measurement network is independent of the structure of the investigation area (e.g., location of streets, residential or industrial areas), the grid arrangement ensures a representative sample of all theoretically possible measurement sites [148]. This strategy makes allowance for the fact that air pollution monitoring of areas necessarily has the character of spot check measurements, at least with respect to the spatial distribution of air pollutants. The density of measurement points on the network determines the resolution of the system; hence structures smaller than the network unit area (e.g., 1 km^2) cannot be detected (e.g., points of high pollution in streets). The frequency of sampling at the measurement points determines the temporal resolution. If continuous measurement is performed (see Section Automatic Measuring Methods), the temporal resolution can be practically perfect, except for periods when the equipment is out of commission.

When using random measurements, not only must the size of the statistical sample be adequate, but also measurement times must be randomly selected to ensure accurate representation of the time dependence. As atmospheric pollution often shows marked variation during the day and correlation with the seasons, measurements only at certain times of the day or certain times of the year would not give representative results.

Random sample measurements are particularly well suited for the determination of annual averages or percentiles not higher than 98 %. For these characteristic values, the additional uncertainty introduced by cost effective random sampling

can be kept reasonably small [163].

Outstanding examples of this basic concept of grid measurements combined with random sampling were the pollution measurements prescribed for the German licensing procedure before 2002.

For general air pollution monitoring larger spacings of the network were chosen, with continuously operating measurement stations 4 – 16 km apart. Several German air pollution networks were designed in this way, e.g., for the Rhine-Ruhr area [148], but were restructured following the “stratification approach” of the European air quality directives [132-137] after 1998.

5.1.2.2. *Evaluation of Data; Period and Frequency of Measurements*

The choice of measurement period and frequency and the evaluation of the results depend mainly on the definition of the assessment criteria (limit values) used. The assessment and measurement systems must complement each other. If the criteria are related to a one-year period, the measurement period must be the same. If, however, alerts or short-term abatement measures are based on periods of 1 – 3 h (e.g., as in the Smog Regulations of the EC Directives [133], [135]) the temporal resolution of the measurements must be smaller than the assessment interval, which makes continuous measurement necessary.

For regulatory purposes (e.g., comparison with limit values), it is generally sufficient to derive two characteristic figures from the statistical sample of measured values: the average pollution (arithmetic mean or median) and the peak pollution (e.g., a 90 or higher percentile). Very high percentiles such as the short-term limit values for SO2 and NO2 in the EC legislation [133] afford continuous measurements, whereas annual means, for example, of benzene [134] or heavy metals [133], [136], can be monitored more economically by spot-check measurements. The additional uncertainty introduced by the incomplete time coverage of the monitoring data can be estimated [159].

The question whether and how the uncertainty of measurement of pollution (e.g., expressed as a confidence interval with a given confidence level) should be taken into account when comparing measurements with limit values is the subject of controversy. An ISO Guideline contains recommendations on this subject [149]. The results of immission measurements are generally compared directly with the limit values.

However, the data-quality objectives for the measurement uncertainty, for minimum time coverage and minimum data capture prescribed in the EC legislation [133-137] limit the overall uncertainty of the measurements.

5.1.2.3. *Planning Measurements on Industrial Plants*

Careful measurement planning is needed for monitoring of air pollution near industrial facilities [164], such as measurements specifically relating to cause analysis in connection with complaints or with plans and programmes to abate air pollution [144]. Such planning can greatly reduce measurement costs compared with schematic use of measurement grids. The assessment of the validity of complaints or of the results of abatement measures for single sources often requires one or two measurement points only, these being located at the place specified by the complainant or the point of the expected maximum pollution and exposure when determining peak and average figures due to a particular source. Such an exposure-related approach is also used to measure the air pollution in the vicinity of a planned or existing industrial facility as part of the German authorization procedure [140]. Generally, two measurement points are selected which are representative for the areas of maximum exposure (combination of background levels and surplus burden of the industrial source calculated by diffusion modeling). One monitoring point should reflect the highest average exposure, and the other the highest peak levels. For cause analysis and the identification of sources of pollution, simultaneous measurements are made upwind and downwind and also evaluated as a function of wind direction. Methods of multivariate statistics, fingerprint or cluster analysis may be used in the case of multicomponent measurements for source identification and quantification [143, 150, 151]. Especially when sources emit several substances simultaneously, with a characteristic emission pattern (e.g., ratios of different hydrocarbons or heavy metals to one other), analysis of the pollution pattern, e.g., as a function of the wind direction, can often enable the main cause or causes to be determined, and in favorable cases even the approximate relative immission contributions [143].

5.2. Quality Assurance

Ambient air measurements can be very costly with respect to capital investment, management, and personnel. Based on the results, very far-reaching decisions can often be made, with considerable economic or ecological consequences. Therefore, quality assurance forms an inseparable part of the measurement system. Quality assurance can be divided into two different categories, which are described in more detail in Sections Procedure-Based Methods and User-Based Methods.

5.2.1. ***Procedure-Based Methods***

Every comprehensive ambient air monitoring method consists of several steps: sampling, sample preparation and cleanup, isolation of the pollutant, detection, data collection, and data evaluation. In a few cases, especially in the continuous measurement of inorganic gases, certain steps of the sequence can be omitted (e.g., separation of the pollutants).

In most types of pollution measurement, extensively documented, comprehensive procedures, covering all steps from sampling to data evaluation and standardized in DIN – ISO Standards, CEN Standards, or VDI Guidelines [152], are recommended (see Chap. Measuring Methods).

For many years, an important part of the documentation of measuring procedures has been the specification of performance characteristics such as

1. Detection limit: the smallest concentration or amount of a substance that can be distinguished from zero with a given probability (e.g., 95 %)

2. Trueness: the degree of agreement between a measured value and the “true” value or an accepted reference value
3. Precision: the degree of agreement between values measured under given conditions by the repeated application of a measuring procedure
4. Measurement uncertainty: a comprehensive indicator for possible deviations of a measurement result from the “true” value (see below)

There are various definitions of these and other statistical concepts. Details can be obtained from [153, 155, 165].

In the past, the comprehensive VDI Guidelines have been of the greatest importance in the standardization of pollution measurement in Germany. However, as the EU became more and more firmly established, the importance of European and international standardization grew rapidly.

The main reason for this development was the new European legislation [133-137], which defines so-called data-quality objectives for minimum time coverage, minimum data capture, and, especially, for maximum measurement uncertainty. As a consequence, all newly developed standards describing reference methods laid down in the EU directives mentioned above must deal explicitly with the evaluation of measurement uncertainty in order to demonstrate that these data quality objectives can be met. The fundamental concept for these evaluations is given by the “Guide to the Expression of Uncertainty in Measurement” (GUM) [146]. The GUM describes a very abstract concept, so many papers were published to give practical guidance for using this concept [154], [166], [167]. But according to European legislation it is not mandatory for the Member States to use the reference methods standardized by CEN, because all directives contain a sentence like this: “A Member State may also use any other methods which it can demonstrate gives results equivalent to the above (reference) method”. A guidance document developed by a European working group describes how equivalence of monitoring methods with the reference method within the required maximum measurement uncertainty may be demonstrated [168]. This concept was recommended for use by the European Commission.

All automated instruments for the measurement of ambient air pollutants should be type-approved. The procedures for this type approval are described in various standards, e.g, in Germany [169-171] and in the UK [172]. Some of the new CEN standards for inorganic gases [173-176] and for benzene [177] also contain corresponding regulations.

5.2.2. *User-Based Methods*

The use of standardized and tested equipment and procedures for the measurement of pollution cannot of itself ensure an acceptable quality of measurement if adequate systems of quality management are not operated by the user.

The ISO 9000 family of standards has been developed to assist organizations in implementing and operating effective quality management systems [178], [179]. Together they form a coherent set of quality management system standards facilitating mutual understanding in national and international trade. But conformity of the quality management system within which a laboratory operates to the requirements of ISO 9001 does not of itself demonstrate the competence of the laboratory to produce technically valid data and results.

For that reason, in the field of ambient air measurement the standard ISO/IEC 17025 (General requirements for the competence of testing and calibration laboratories) is of much more relevance [180]. Over several years this standard and those of the ISO 9000 series were harmonized. That means that testing and calibration laboratories that comply with the 17025 International Standard will therefore also operate in accordance with ISO 9001.

The 17025 standard specifies the general requirements for the competence to carry out tests and/or calibrations, including sampling. It covers testing and calibration performed using standard methods, nonstandard methods, and laboratory-developed methods.

The standard consists of two main parts. The part “management requirements” deals, e.g., with organization, document control, contracting and subcontracting, customer service, preventive and correcting actions, control of records, and auditing. “Technical requirements” include personnel, environmental conditions, test and calibration methods and method validation, estimation of measurement uncertainty, data control, measurement traceability, use of reference standards and materials, and reporting.

Many technical tasks in implementation of the European air quality directives may be performed only by laboratories working in accordance with this international standard. A formal accreditation based on ISO/IEC 17025 is internationally recognized as proof of competence.

Another important element of quality assurance is the national reference laboratories (NRL), which had to be notified by all European Member States within the implementation of the air quality directives. The NRL must coordinate and harmonize quality assurance measures on national level and participate in European programmes organized by the European Commission. The NRL are organized in AQUILA, the Network of Air Quality Reference Laboratories [181]. AQUILA includes the EFTA countries and the EU candidate countries.

A further important element of quality assurance is interlaboratory comparison, [182], [183]. In air pollution measurement technology, this is mainly carried out with the aid of air sample distribution equipment [184], [183] which enables standard gas mixtures and aerosols of widely different compositions and qualities to be produced and supplied. A number of participating laboratories take samples repeatedly from the same gas/aerosol supply and analyze them chemically. These data are then statistically analyzed, enabling important conclusions to be drawn regarding measuring procedures and participants (measurement uncertainty, accuracy, precision, repeatability, comparability). Interlaboratory comparisons are performed on national levels [182], [183] as well as on international level, e.g. in the framework of AQUILA [185].

Also, interlaboratory testing is an important element of notification by the Länder of institutes to carry out measurements in accordance with § 26 of the Air Pollution Control Act (BImSchG). This is a special variation of an accreditation procedure

based on the International Standard ISO/IEC 17025.

Last but not least, measures of quality assurance and quality control are an extremely important element in routine monitoring. As well as the systematic repair and maintenance of all measuring equipment and rectification of faults, regular calibration and monitoring of functions are essential. Many of those measures are mandatory within the implementation of the new CEN standards described in Measuring Methods [173-176].

5.3. Measuring Methods

5.3.1. *Measuring Methods for Inorganic Gases*

A very wide range of automatic and manual measuring methods is available for inorganic gases [152, 173-176], [186], [187], [188].

5.3.1.1. *Automatic Measuring Methods*

A large number of continuously measuring monitors are available for the substances sulfur dioxide, nitrogen oxides, carbon monoxide, and ozone. These are very widely used, especially in monitoring networks. As a consequence of the European Directives on ambient air quality [133-135], these methods were standardized by CEN [173-176]. The main parts of these standards describe a procedure of systematic type approval (see also Procedure-Based Methods). The German Ministry for the Environment, Nature Conservation, and Nuclear Safety declares on a regular basis that certain types of equipment, produced by various manufacturers, are suitable for air pollution measurement [188], [189]. The main features of the individual methods are listed in Table 7.

Table 7. Automatic measurement methods for inorganic gases

Substance	Measurement principle	Comments	Refs.
SO_2	UV fluorescence; excitation of SO_2 molecules by UV radiation (200 – 220 nm); measurement of the fluorescence radiation (240 – 420 nm)	spurious reactions (e.g., with hydrocarbons) must be eliminated by filters	[174]
NO/NO_2	chemiluminescence; reaction of NO with O_3 to form NO_2; detection of chemiluminescence radiation by photomultiplier	NO_2 only indirectly measurable; use of converters to reduce NO_2 to NO; measurement of NO and NO_x (= NO + NO_2) in separate measurement channels; converter efficiency must be determined	[173]
CO	nondispersive infrared absorption; measurement of IR absorption by substance-specific detector with reference cell	reference: a) cell with N_2; b) sample air after selective removal of CO by catalytic/chemical reactions; c) optical removal of the CO absorption (gas filter correlation)	[176]
O_3	UV absorption; stabilized low-pressure Hg lamp as radiation source (253.7 nm); recording of the UV absorption according to the Lambert – Beer law; detector: vacuum photodiode, photomultiplier	single- and double-cell instruments; reference: air sample after selective removal of the ozone by chemical/catalytic reactions (e.g., Cu/MnO_2)	[175]

According to the regulations foreseen in the European Directives, measurement results generally must be reported at 20 °C and 101.3 kPa. Therefore, most automated instruments are equipped with sensors measuring temperature and pressure in the measuring cell for appropriate correction.

Another important gas for which an automated measuring method is available for is ammonia. In a multistep process NH_3 penetrates Teflon membranes and is finally dissolved in purified water. The increase in conductivity of this solution is a measure for the ammonia content in the air [190]. A commercial instrument is available.

All automatic measuring methods based on physicochemical principles must be calibrated using calibration gases traceable to national standards. This even applies to the measurement of ozone by UV absorption, although this in principle is itself a reference method under controlled conditions. Experience shows that knowledge of extinction coefficients at 253.7 nm coupled with the validity of the Lambert – Beer law does not ensure that measured values will be automatically correct. For example, soiling of the gas passages, malfunction of the internal ozone scrubber for the quantitative decomposition of the ozone in the reference measurement cycle, or electronic defects can lead to significant false readings.

5.3.1.2. *Calibration of Automatic Measuring Methods*

All automated instruments for the measurement of inorganic gases must be calibrated using calibration gases traceable to national standards. The new CEN standards defined as reference methods for the implementation of the European Directives on air quality [173-176] require such calibration at least every three months. Various methods for the generation

of calibration gases are described in ISO standards or German VDI guidelines [191-202], [228]. The appropriate application of these methods requires specific equipment and experienced staff. In calibration laboratories for ambient air measurement especially the following methods are used in practice: static dilution [190], thermal mass flow controllers [198], diffusion [199], and permeation [202]. In addition, certified gas standards are commercially available in pressure cylinders.

Automatic measuring equipment is mainly used in measurement stations, and these often form a part of a pollution measurement network (see Section Measurement Networks (General Air Pollution Monitoring)).

As the equipment is operated under these conditions for long periods of time (sometimes several weeks) without direct personal supervision, it is essential to monitor their correct function by using an automated procedure on a regular basis. An essential requirement for this supervision is the availability of test gas generators, which supply blank samples and standard gases to the measuring equipment.

A blank sample gas is one in which the concentration of the substance to be measured and for which the equipment is being calibrated is present at only trace concentrations, below the detection limit of the measuring method. Blank sample gases must not contain substances that react with the component to be measured or interact in any other way. A test gas is a gas mixture which usually consists of a carrier gas (nitrogen, air) with one or more added components [186-188], preferably produced by dynamic test gas generators [228].

Nitrogen or synthetic air in pressurized gas cylinders can also be used as blank gases. Such blank gases are relatively easy to handle, but often have the disadvantage in pollution technology that their properties differ from those of the matrix air being analyzed (e.g., in moisture content). There is also the necessity for preparing and changing the gas cylinders. Therefore, blank gases are preferably prepared immediately before use from the air to be analyzed, e.g., by filtration through sorbents.

For many substances, standard gases can be obtained commercially in pressure cylinders. If the gas cylinders contain the standard gas in the concentration required, dilution is unnecessary. However, with such standard gases there are problems of high gas consumption and sometimes poor storage stability, which usually decreases with decreasing concentration. Alternatively, gas cylinders can be used in which concentrations are 50 – 100 times as high as that required in the standard gas. In this case, controlled dilution must be carried out with the base gas. A standard gas generator operating on this principle is more expensive, and the dilution stage is a additional source of measurement uncertainty. Advantages include the generally better storage stability and lower rate of consumption of the bottled gas.

The standard gas mixture can also be prepared by permeation, or, in the case of nitrogen oxides, by gas-phase titration [229], [230]. The most important methods used for preparing standard gas mixtures containing components measured in pollution measurement networks on a routine basis are indicated in Table 8.

Table 8. Production of test gases for calibration

Component		Atmosphere	Pressure cylinder (direct)	Pressure cylinder (with dilution)	Permeation	Gas-phase titration
SO_2	blank gas	x	x			
	test gas		x	x	x	
NO	blank gas	x	x			
	test gas		x	x		x
NO_2	blank gas	x	x			
	test gas		x	x	x	x
CO	blank gas	x	x			
	test gas		x	x		
O_3	blank gas	x	x			
	test gas	x				

According to the CEN standards [173-176] all these transfer standards used as test gases in field measurements must be checked at least every six months using calibration gases traceable to national standards. Zero and span checks have to be performed at least every two weeks; 23 or 25 h are recommended.

5.3.1.3. *Manual Methods*

In manual measuring methods for inorganic gases, the substance to be measured is generally absorbed in a solution or adsorbed on a solid material during sampling. In most cases, this is followed by a color reaction and photometric determination. Because the personnel requirement is comparatively high, these are seldom used for field measurements if alternative automatic methods are available. The most important methods are briefly outlined in Table 9.

Table 9. Manual measurement methods for inorganic gases

Substance	Method	Details	Comments*	Refs.
SO_2	TCM method	absorption in tetrachloromercurate solution (wash bottle); reaction with formaldehyde and *p*-rosaniline to give red-violet sulfonic acid; photometric determination	DL = 0.2 µg SO_2; s = 3 µg/m^3 at 140 µg/m^3	[203], [204], [205]
NO_2	Saltzman method	absorption in reagent solution to form a red azo dye (wash bottle); photometric determination	calibration with sodium nitrite; DL = 3 µg/m^3;	[206], [207], [208]
F^-	silver bead method; variant 1	sampling with dust removal; concentration of F^- on silver beads coated with sodium carbonate; elution and measurement with ion-sensitive lanthanum fluoride electrode	simultaneous detection of an unknown proportion of particulate fluoride pollutants	[209]
F^-	silver bead method; variant 2	sampling with heated membrane filter; concentration of F^- on silver beads coated with sodium carbonate; determination by electrochemical method (variant 1) or photometrically (alizarin-complexone method)	danger of low results due to partial sorption of gaseous fluoride pollutants on membrane filter; DL = 0.5 µg/m^3	[210]
Cl_2	methyl orange method	decolorizing reaction with methyl orange solution (wash bottle); photometric determination	DL = 0.015 mg/m^3	[212], [213]
NH_3	indophenol method	absorption in dilute H_2SO_4 (impinger/wash bottle); reaction with phenol and hypochlorite to form indophenol dye; photometric determination	DL = 3 µg/m^3 (impinger); partial simultaneous detection of NH_4 compounds and amines	[214]
NH_3	Nessler method	absorption in dilute H_2SO_4 (impinger/wash bottle); distillation and reaction with Nessler's reagent; photometric determination	DL = 2.5 µg/m^3 (impinger); partial simultaneous detection of NH_4 compounds and amines	[219]
NH_3	Denuder with H_3PO_4 coating	flow injection analysis	DL = 0.1 µg/m^3	[216]
NH_3	Denuder with citric acid coating	analysis with indophenol method	DL = 0.1 µg/m^3	[217]
H_2S	molybdenum blue method	sorption as silver sulfide on glass beads prepared with silver sulfate and potassium hydrogen sulfate (sorption tube); liberation as hydrogen sulfide and reaction to form molybdenum blue; photometric determination	DL = 0.4 µg/m^3	[218]
H_2S	methylene blue method	absorption in cadmium hydroxide suspension to form CdS; liberation of H_2S; reaction to form methylene blue; photometric determination	DL = 0.3 µg/m^3	[219]

* DL = detection limit; *s* = standard deviation.

For several decades, sulfur dioxide was regarded as the most important atmospheric pollutant. Consequently, this substance was included in most pollution measurement programs, and some methods for measuring pollution by sulfur dioxide exist, e.g., the tetrachloromercurate (TCM) method [204], [205]. However, due to significant decrease of SO_2

concentration in air in most parts of Europe, these methods are of minor importance today.

The Saltzman method [206-208] was an important manual method for nitrogen dioxide in the past.

Samples for measuring pollution by hydrogen fluoride and fluorides can be taken by sorption tubes [209], [210], special filters, or denuders (diffusion separation tubes). Analytical determinations are mainly based on photometric, electrochemical, or ion chromatographic methods [186], [211].

Pollution by chlorine and chlorine compounds is seldom measured in practice, as chlorine itself occurs very rarely and in very few locations because of its high reactivity.

Ammonia in the atmosphere is in chemical equilibrium with ammonium compounds, so that NH_3 and NH_4^+ compounds are often determined together. For a long time, the most important manual methods were the indophenol method [214] and the Nessler method [215].

A special sampling method, mainly used in conjunction with manual measurement, is based on the diffusion separation tube (denuder), which separates the gaseous phase from the particulate phase by means of different diffusion rates. It is therefore mainly used for difficult separation problems involving systems of this type [220]. In the classical denuder technique, the air sample is drawn through a glass tube with a coating which depends on the substance or substances to be determined [221-224]. For example, in the determination of basic components such as ammonia and ammonium compounds, tubes coated with an acidic substance (e.g., H_3PO_4, oxalic acid or citric acid) are used [216], [217]. The gaseous substances are deposited and fixed on the tube wall by chemical reaction, while the particles mainly pass through the tube and can be collected on a filter.

Many variations of the denuder technique have been developed, some of which have been automated (annular gap denuders, wet denuders containing solutions of reagents, thermodesorption denuders) [225], [226]. Denuders are the preferred method for sampling systems such as ammonia/ammonium compounds, nitrogen oxides/nitric acid/nitrates, sulfur oxides/sulfuric acid/sulfates, or hydrogen halides/halides. The denuder technique has much extended the possibilities of taking differentiated samples. However, depending on the particular version of the method, it needs a comprehensive laboratory, and correct use of the technique requires great experience.

5.3.2. *Measurement and Analysis of Particulate Atmospheric Impurities*

For the assessment of particulate atmospheric impurities, not only their concentration — expressed as mass per volume or number of particles per volume — but also their size distribution is of paramount importance. In addition, parameters such as the surface area and the composition of the aerosol are currently strongly discussed in relation to health effects [227].

The size distribution of particles in ambient air varies from aerodynamic diameters [231] of a few nanometers to more than 100 µm [232]. The very coarse particles at the upper end of this distribution are deposited quickly on the ground by virtue of their size and density and are therefore not homogeneously dispersed in ambient air; this fraction is characterized as deposited dust (Section Measurement of Total (Bulk) Deposition). The atmospheric particles, which are quasihomogeneously dispersed, are classified as suspended particulate matter (SPM).

The borderline between the two regimes cannot be exactly drawn and depends in a complex fashion on many exterior conditions. However, as a rule of thumb it can be stated that suspended particulate matter mainly consists of particles smaller than 30 µm [233] in aerodynamic diameter.

5.3.2.1. *Measurement of Particle Mass and Particle Fractions*

How deeply particulate matter (SPM) may penetrate into the human respiratory system depends mainly on the size of the particles. Experiments have shown that all fractions of SPM are inhalable (inhalable fraction) [231], but that coarser particles with aerodynamic diameters > 10 µm are mainly deposited within the nose and throat [234]. Particles smaller than 10 µm can penetrate beyond the larynx (thoracic fraction) [231], whereas particles finer than about 4 – 5 µm in the case of healthy adults and with median diameters below 2.5 µm in the case of children or infirm persons with narrower respiratory passages are fully respirable (respirable fraction [231]).

In health-related sampling of particles, there is no clear cut off between the different fractions, and conventions defining the size distributions of the fractions are needed. Conventions which are valid likewise for ambient air and the workplace atmosphere have been laid down in ISO 7708 [231]. The definition of inhalable more or less corresponds to SPM, the thoracic convention (PM 10) comprises particles with a median aerodynamic diameter of up to 10 µm, and particles designated as respirable for persons at high risk (PM 2.5) have a median diameter of 2.5 µm [231].

In Figure 5, these conventions are compared with measured size distributions of particles in ambient air, which are typically bimodal. The thoracic convention (PM 10) cuts the peak of the coarse particles, whereas the PM 2.5 convention fully includes the fine-particle mode.

Figure 5. Measured size distribution of particles in ambient air (Bilthoven, Netherlands) in comparison with the conventions laid down in ISO 7708

The bimodal distribution points to different processes of particle generation in the atmosphere [232]. Whereas the coarse mode is predominantly caused by mechanical processes such as the resuspension of dust from surfaces, the fine mode consists of particles which stem from nucleation and condensation.

Bearing in mind the deeper penetration of finer particles into the airways, it is not surprising that the PM 10 and particularly the PM 2.5 burden have been shown to correlate better with health effects than the concentrations of coarser particles [231], [235], although recent research has shown that the effects of coarser particles cannot be neglected [236]. Consequently, air quality standards in European countries [133] and in the USA [237] are based on particle fractions and hence afford the fractionating measurement of SPM for compliance checking.

The majority of dust measurements, both fractionating and nonfractionating, are based on a mass determination of particles on glass-fiber or membrane filters [230]. This is followed by a gravimetric determination (manual methods) or, in the case of continuously operating instruments, by radiometric measurements or oscillating microbalances (Table 10). Different validated sampling heads are used to select the particle fractions to be measured (TSP, PM 10, PM 2.5, and PM 1.0). These sampling heads use the phenomenon of impaction (separation based on inertial forces) to preseparate the coarse particles. The air stream within the sampling head is diverted in such a way that only particles smaller than the selected diameter can follow the air stream and are collected on a backup filter. The coarser particles are trapped in fractionators before the filter. The fractionators necessary for the different particle fractions can be calculated and tested with model aerosols, but the collection efficiencies of the different sampling heads do not exactly match the conventions laid down in ISO 7708 [231].

As the object of measurement — SPM or a fraction thereof — is not sharply defined, and variations in concentration, particle-size distribution, and composition can occur with time and location, there is no absolute measuring method. To a certain extent, each applied method defines its measurement object, and the interconversion of measured values obtained with different methods is only possible under carefully controlled conditions. Consequently, reference methods have been laid down which give by convention the “correct” results, and the equivalence of other methods has to be validated by test measurements in comparison with the reference procedures [168]. The European union [133] has laid down the gravimetric WRAC instrument as reference method for PM 10. A CEN standard [238] describes how validation measurements with other methods against this standard have to be performed. One low-volume sampler (Table 10) and one high-volume sampler are also described in the CEN standard as reference methods [238] for field tests after comprehensive validation measurements in comparison with the WRAC sampler. A CEN reference method for PM 2.5 measurements [239] describes the design of a high-volume and a low-volume gravimetric sampler.

Table 10. Measurement methods for SPM

Method (examples)	Measurement principle (examples)	Comments	Refs.
Low-volume sampler	fractionating and nonfractionating sampling; air flow rate 2.3 – 2.8 m^3/h (small filter equipment) or 1 m^3/h (Partisol); filter diameter 47 – 50 mm; gravimetry; volume measurement by revolving vane anemometer	low noise; easy operation due to small size and low weight; control by time-control switch; also available with PM 10, PM 2.5 and PM 1.0 sampling heads (impactors), European reference method (PM2.5)	[254], [255], [239]
High volume sampler	detection of particles < ca. 30 µm diameter; air flow rate ca. 30 – 100 m^3/h; filter diameter 130 – 257 mm; gravimetry; volume measurement by flow meter	recovery of large amounts of dust, useful for analysis of dust components; high noise level; also available with PM 10 and PM 2.5 sampling heads (impactors), European reference method (PM 2.5)	[256], [257], [239], [258]
Radiometric beta gauge instrument	continuous radiometric dust measurement equipment; fractionating and nonfractionating sampling; air flow rate 1 or 3 m^3/h; dust collection on filter band; dust measurement by attenuation of β-radiation on passing through exposed filter (ionization chambers) or Geiger counter	gravimetric calibration by known amounts of dust on single filters and intercomparison with gravimetric reference method; operation with PM-10 and PM2.5 sampling heads possible	[259], [260] [261], [262], [263]

Oscillating microbalance	continuous dust measurement equipment; fractionating and nonfractionating sampling; air flow rate 1 m^3/h; dust collected on filter (which is part of a vibrating system with resonance frequency) in side stream (3 L/min); recording of frequency decrease with increase in dust load on the filter	relationship between frequency decrease and mass of dust must be established by calibration and intercomparison with gravimetric reference method; operation with PM 10 and PM 2.5 sampling heads possible	[264], [265]
Optical analyzer	light-scattering device using a laser light source orthogonal to the sampled air stream. Particles (> 0.3 μm) are counted and classified. Variant: parallel radiometric dust measurements for in situ calibration	PM 10, PM 2.5 and PM 1.0 can be monitored simultaneously. Conversion of counts to particle mass depends on nature of particles. Suited for screening measurements if there is no on situ calibration	[266, 267]
WRAC (wide-range aerosol classifier)	fractionating sampling; four impactors (10 µm, 21.8 µm, 40.3 µm, 65.4 µm) running parallel; air flow rate 77.9 m^3/h (PM 10 stage)	European PM 10 reference method; difficult handling in the field, not for routine operation	[238]

The continuous monitoring of PM 10 and PM 2.5 fractions (either radiometric, by microbalances, or by optical methods; see Table 10) is still subject to some difficulties, because validation measurements with the reference methods have revealed deficiencies on the order of 30 wt % or more [232], [268], [269]. Hence, correction factors or equations must be established by intercomparison measurements with the reference methods, and the results have to be corrected accordingly [133], [268].

It has been demonstrated that the mass losses of PM 10 or PM 2.5 of automatic instruments compared with the reference method are mainly due to the evaporation of semivolatile aerosols such as ammonium nitrate in the heated sampling tube or on the filter [269], [270]. Some heating is necessary (typically 50 °C for the older instruments) to avoid condensation of water vapor. Also the gravimetric reference methods are not free from artefacts and may loose some semivolatiles when sampling head and tube heat up on hot summer days [232].

Various recent improvements have reduced or allowed the quantification of the loss of semivolatiles in continuously operating instruments. The instruments were modified to operate at lower temperatures. In the case of the TEOM, a diffusion dryer was placed before the filter unit to remove moisture and to enable operation of the filter at 30 °C (TEOM SES [271]). New versions of the beta gauge instruments (e.g., FH62IR or MP101M) were equipped with controlled heating devices (TRS) which keep sampling line and filter unit only several degrees Celsius above ambient temperature [267]. The differential TEOM uses two sensor units, which are alternatively switched on and off out of phase, so that alternatively one sensor is driven with particle free air, and the other with particle-burdened air [272]. The sensor in the particle-free air stream measures the “artefacts” (e.g., evaporation), and the output signal can be corrected accordingly. A further improvement uses a cooled filter unit upstream of only one sensor unit. Alternatively, the air stream bypasses the cooled filter or is cleaned from particles. The same sensor thus alternatively measures the particle mass and possible artefacts (TEOM FDMS) [273].

Discontinuous gravimetric sampling of SPM or fractions thereof is facilitated by automatic filter changers that store a large number of filters and supply them in sequence to the sampling device. The exposed filters are stored on site in a cooled magazine [274].

The black smoke method [138], [275], [276], formerly widely applied in the United Kingdom and other European countries, is a combination of filter precipitation of dust and an optical method. Air is drawn through a filter paper at a low rate (ca. 2 m^3/d), and the darkening of the filter is then measured with a reflection photometer. This black smoke value is converted into gravimetric units (µg/m^3) by means of a calibration curve [277], [278], [279]. However, this calibration curve depends on the composition of the particles (e.g., their soot content) and is both site- and season-specific. Notwithstanding these shortcomings, the results of black smoke measurements are still of value, because many epidemiological studies were based on them [280] and show a clear correlation with negative health effects.

5.3.2.2. *Measurement of Particle Numbers and Size Distributions*

Particle mass is not the only metric which correlates with health effects. Some studies suggest that high numbers of particles, especially of ultrafine particles (< 0.1 μm), may be of equal or more importance for some detrimental effects such as cardiovascular disease [240], [241]. Consequently, measurements of the size distribution and the number of particles are gaining in importance. As particle numbers are dominated by the ultrafine fraction, which on the other hand adds almost nothing to particle weight [232], ultrafine particles are generally measured as numbers.

Condensation particle counters (CPC) [242], [243], [244] measure particle numbers directly in the range of 3 nm to 2 mm. Ambient air passes through a chamber filled with supersaturated vapor (butanol or water) and then through a second cooled tube, where the fluid condenses on the particles. The particles grow to approximately the same size and can be counted by an optical detector. However, information on particle size is lost by the condensation step. Information on the size distribution can be obtained in combination with a separation unit upstream of the CPC.

Without a condensation step, optical particle counters can only be used down to a particle size of about 100 nm [245],

[246]. They measure the light which is scattered by single particles and count the events. Lasers or high-pressure Xe lamps are used as light source. The intensity of the scattered light is proportional to the particle size, so that information on size distribution and number can be obtained simultaneously (laser aerosol spectrometer, LAS [247]).

Size distributions in the range from several nanometers up to several micrometers can be measured by a scanning mobility particle analyzer (SMPS) [248], [249], [244]. The polydisperse aerosol is charged by a beta radiation source (85Kr) and then passes into a cylindrical electrostatic classifier (DMA). The wall of the cylinder serves as outer electrode, whereas the inner electrode is situated in the center of the cylinder. The inner cylindrical part of the DMA is flushed with particle-free air, and the sample air stream is introduced near the outer electrode. The potential difference between the electrodes allows only particles with a given mobility and diameter to pass through a narrow outlet at the end of the cylinder. Small particles with a large mobility are collected by the inner electrode, whereas large particles with low mobility are swept through by the flushing air stream. The exiting particles within a narrow size range are counted by a condensation particle counter (CPC). The particle size range is scanned by changing the electric field strength.

Another particle size analyzer applicable in the size range > 500 nm up to 10 μm uses a critical orifice to accelerate the air stream. The acceleration of the particles and their velocity depends on their aerodynamic diameter. After the orifice, the velocity of the particles is measured by two partly overlapping laser light beams (aerodynamic particle sizer, APS [250]), which directly gives information on the aerodynamic particle diameter.

Other principles which are used to measure particle size distributions are electrical low-pressure cascade impactors (down to particle diameters of 30 nm) and diffusion batteries combined with condensation particle counters [245], [251], [252]. In order to cover the full particle size range, generally a combination of instruments (e.g., APS or LAS and SMPS) must be applied.

5.3.2.3. *Measurement of Inorganic Components in Suspended Particle Matter*

Suspended particulate matter in ambient air is a complex mixture of miscellaneous components such as elemental carbon, high-boiling compounds (organic carbon), partly water soluble ionic compounds, silicates and other crustal material, sea salt, and heavy-metal compounds. Typical compositions of particles can be found in [250], [253]. Whereas crustal material is considered as relatively inert with respect to human health [235], other toxic and carcinogenic components such as soot, heavy-metal compounds, and fibers can significantly enhance the health effects of particles [235]. Consequently, measurement methods have been developed to analyze these toxic and carcinogenic ingredients of the aerosol separately. In addition, the analysis of the composition of the atmospheric aerosol gives valuable information on the origin of the aerosols and is an important tool for source apportionment [250]. In the following section, measurement methods for inorganic components are described, whereas the analysis of important organic constituents of the aerosol is dealt with in Measurement of Organic Atmospheric Pollutants.

5.3.2.3.1. Measurement of Major Ionic Compounds in Suspended Particulate Matter

Although the major ionic compounds in suspended particles are nontoxic (sea salt) or less toxic (ammonium sulfate), these compounds are of special interest because they are constituents of secondary aerosols (ammonium, nitrate, sulfate) and of sea salt aerosols (sodium, chloride) so that analysis of these compounds can give valuable information on the origin of the collected aerosols [250].

For the analysis of the water-soluble compounds ammonia, nitrate, chloride, and partially sulfate the filter with the absorbed particles is extracted with water, e.g., in an ultrasonic bath. The obtained solution can be analyzed by ion chromatography according to the methods of water analysis [281]. Sodium, potassium, magnesium, and calcium can be analyzed together with the other metals (see below).

5.3.2.3.2. Measurement of Heavy Metals and Metalloid Compounds in Suspended Particulate Matter

Metal compounds in SPM samples are often determined on a routine basis; minimum requirements for sampling and analysis are described in the EU council directive on ambient air quality assessment and its daughter directives [133], [136].

The SPM and its PM 10 fraction is first collected on filters (see Measurement of Particle Mass and Particle Fractions) and is then usually chemically digested to bring the metal and metalloid compounds into aqueous solution before analysis by standard methods. The most important of these are inductively coupled plasma mass spectrometry (ICP-MS) [282], inductively coupled plasma optical emission spectroscopy (ICP-OES) [283], and atomic absorption spectrometry (AAS) [284].

For ICP-MS the inductively coupled plasma is produced in an ionized gas (argon) in a high-frequency field and acts as the ion source for mass spectrometry of the elements of the solution, sprayed into the argon stream. Although this method is expensive it is now the standard method for the analysis of heavy metals in environmental samples because of its high sensitivity and its ability to analyze many elements in a very short time. In addition, it is the European reference method for the analysis of arsenic, cadmium, lead, and nickel in PM 10.

The inductively coupled plasma can also be used as the atomizing and excitation source. In the ICP-OES technique the emission of the excited elements is analyzed. Compared to ICP-MS the method is less expensive but less sensitive.

Atomic absorption spectrometry is a reliable and relatively simple routine method, and is still an important standard method in the field of pollution measurement [285]. The flame technique is only rarely used because of its low sensitivity, but the graphite furnace technique has also been selected as a European reference method for the analysis of arsenic, cadmium, lead, and nickel in PM 10

Other methods for determining metal compounds in SPM include X-ray fluorescence analysis (XRF), polarography, and

neutron activation analysis, but they are only rarely used [285]

Analysis of metal compounds in SPM by conventional methods does not distinguish between the various oxidation states of the elements or between their different compounds. In many cases, a determination of the total metal present is sufficient. However, with certain metals, especially those with carcinogenic properties (As, Cr, and Ni), this further information would be desirable.

There are often large differences in carcinogenicity not only between elements but also between different compounds of the same element (e.g., only chromium compounds of oxidation state VI are carcinogenic). In such cases, specific determination of individual compounds (specification) would be desirable. In spite of the importance of this problem, such specification in pollution measurement is only at the experimental stage. Some progress has been made in speciation of arsenic, chromium, and nickel [286-289].

5.3.2.3.3. Measurement of Soot (Elemental Carbon)

Soot emitted from diesel engines has become relevant since it has been classified as carcinogenic [290], [291]. In addition, soot (elemental carbon) is an important component of the aerosol.

Owing to the variable and complex composition of diesel soot and because some of its constituents are also emitted from other sources, there is no specific method for measuring it. However, existing methods used for workplace monitoring have been adapted to enable reliable figures for the concentrations to be expected in outdoor air to be obtained [292-294]. The fraction of PM 10 in a certain volume of air is separated by a preliminary separator and collected on a glass- or quartz-fiber filter. After solvent extraction and thermodesorption of organic constituents, the elemental carbon content as a measure for the soot concentration the carbon is determined by combustion in a stream of oxygen and coulometric titration of the carbon dioxide formed. In Germany this coulometric method is now the reference method for measurement of soot. at sites influenced by road traffic [296]. In the USA a more sophisticated method is used. Charring of organic material during the thermodesorption step is measured by optical reflectance and the amount of thus-formed elemental carbon is subtracted from the result [297].

Optical determination of the soot content of the dust can be carried out using an aethalometer, based on the light transmission of an exposed dust filter compared with a reference measurement on the unexposed filter. The concentration can be calculated from the light attenuation, using an empirically determined absorption coefficient for particulate elemental carbon and the volume of air passed through the filter. The aethalometer values show good correlation with the coulometric method, but the absorption coefficient is dependent on the specific site [298].

5.3.2.3.4. Measurement of Fibers

Some fibers are classified as carcinogens [299]. Carcinogenic fibers have a diameter of $d \leq 3$ μm and a length $l \geq 5$ μm, where $l : d \geq 3$. These fibers may consist, for example, of asbestos, minerals, or ceramic material (MMVF, man-made vitreous fibers). In the past, asbestos fibers were most important. As a consequence of the prohibition of manufacturing and use of asbestos-containing products, measurements of asbestos fibers in ambient air are now of only minor significance. Fiber concentrations are mostly below the detection limit of the measurement methods (300 fibers/m^3). During recent years, interest has shifted more to other types of fibers, e.g., the MMVFs mentioned above. The concentration of other (i.e., non-asbestos) inorganic fibers may be on the order of some hundreds to some thousands of fibers per cubic meter of ambient air.

Measuring methods for fibrous materials depend on collecting the fibers on filters and counting them under a microscope [300], [301].

Methods of measuring fibers in the atmosphere use the electron microscope. Samples are taken on gold-coated capillary membrane filters and ashed on the filter by oxygen plasma treatment to remove organic substances. The fibers on a randomly selected part of the filter surface are then counted according to defined fiber counting rules under the scanning electron microscope (SEM) and classified according to their fiber type. Classification is based on energy-dispersive X-ray analysis (EDXA), which can distinguish between chrysotile, amphibole asbestos, calcium sulfate, and other inorganic fibers. The fiber numerical concentration is then calculated using the fiber count result, the examined filter area, and the volume of sample air drawn through this filter area.

Under the usual conditions of measurement and counting recommended in the guideline (1 m^3 sampled air per cm^2 filter surface, 1 mm^2 filter surface inspected), the detection limit is 300 fibers per cubic meter. The whole procedure is very complex and requires great care to obtain reliable results.

5.3.3. ***Measurement of Deposition***

5.3.3.1. *Measurement of Total (Bulk) Deposition*

A common method of measuring deposited dust is the Bergerhoff method. The entire material deposited from the atmosphere (dry and wet deposition) is collected in vessels for 28 – 32 d at ca. 1.5 – 2.0 m above ground level (bulk deposition). The collection vessels are then taken to the laboratory and processed (filtration, evaporation of the water, drying, weighing). The result is quoted per unit area of the collecting surface of the vessel and per unit of exposure time, i.e., in grams per square meter per day. According to, the detection limit is 0.035 g m^{-2} d^{-1}.

Total deposition can also be collected by using funnel – bottle combinations, as are frequently used in the EMEP measuring network [302].

All measurements of deposited dust are relative values that depend on the apparatus used, as the recovery of dust is influenced by air flow behavior and other apparatus-dependent parameters. Measurements by different methods can differ

by as much as 50 % [186].

5.3.3.2. *Measurement of Wet Deposition*

Wet deposition (in rain, snow, fog, and dew) and dry deposition are the two routes which harmful substances can pass from the air to the ground, groundwater, or the surface of vegetation. The measurement of wet deposition has therefore been carried out for some decades as part of the study of environmental problems such as the acidification of soil and lakes and the destruction of forests. For example, the European EMEP measurement network [302] has measured the rate of deposition of sulfate and nitrate anions and some cations, and also the pH of the precipitation at ca. 90 measurement stations. There are also many measurement grids in the United States [303]. Unlike the concentration in the air and the directly correlated dry deposition, the fluctuations in the concentration of atmospheric pollution in rain are relatively small, so that a representative measurement of wet deposition can be performed with a wide-mesh grid. Wet deposition in Germany is traditionally measured by the wide-mesh grid of the Federal Environmental Office [304], rather than by the air measurement stations of the Länder.

To completely separate the measurement of wet deposition by rain and snow (fog and dew represent special problems) from the measurement of total deposition (bulk deposition) and dry deposition, rain collectors are used whose sampling orifices are covered during rain-free periods (wet only samplers [305]). Rain sensors, mostly depending on the principle of conductivity change, trigger the removal of the cover at the beginning of a period of rain and its replacement at the end. A review can be found in [306].

The collecting vessel consists of a funnel (collection area ca. 500 cm^2 or more [305]) and the collection vessel itself, which should be thermostatically controlled and kept in dark conditions to avoid artifacts. (Rain in collecting vessels exposed to light stimulates the growth of algae, and organic micropollutants may undergo photochemical degradation by, for example, H_2O_2 or other peroxides.) Special methods must be used to avoid artifacts and the decomposition of sensitive substances. If the collected precipitation is to be analyzed for inorganic substances, the funnel and collection vessel should be composed of materials such as polyethylene or polypropylene. If organic constituents are also to be measured, borosilicate glass is preferable.

5.3.3.3. *Special Sampling Devices for Deposition Measurements*

Totalizators are used to determine both the wet deposition and the approximate dry deposition (on a standardized model surface). The totalizator consists of a funnel and a sample receiver for measuring the wet deposition and a vessel (often a standardized glass jar for measuring dust deposits, see Section Measurement of Total (Bulk) Deposition) for collecting the dry deposition. A rain sensor is used to switch from wet to dry collection and vice versa.

Snowfall cannot always be detected with certainty by the sensors of rain collection equipment. The best method for measuring snow is therefore still to collect it on an exposed plastic sheet.

The sampling of fog, clouds, and dew requires special equipment. Fog and cloud water can be collected actively by impactors [307] or passively by mesh screens [307]. The latter consist of plastic fibers from which the collected water from the fog or cloud runs into the collection vessel. Dew samples are collected on cooled glass surfaces [308], although it is doubtful whether this method corresponds exactly to the behavior of natural surfaces.

Dry deposition can be collected on adhesive films [309] or in more complex systems [310].

5.3.3.4. *Analysis*

If only dry deposition is collected or if the collected deposition is dried before analysis, analytical methods used are fundamentally the same as those used in the analysis of SPM.

Collected rain water can usually be analyzed for inorganic constituents without preliminary sample preparation, and samples need preliminary centrifugation or filtration only if there is visible cloudiness. Heavy metals can be analyzed by the methods described in Measurement of Heavy Metals and Metalloid Compounds in Suspended Particulate Matter. Routine measurements are also made of conductivity, pH, important anions (NaO_3^-, Cl^-) and cations (Ca^{2+}, K^+, Mg^{2+}, Na^+, NH_4^+, etc.) [304], and also, for research purposes, unstable trace substances and intermediates such as H_2O_2 and HSO_3^-.

The analytical methods used are those generally available for aqueous solutions such as conductivity measurement [311], pH measurement by electrodes [311], [281].

Organic components are extracted from rainwater (e.g., with dichloromethane or toluene). Analysis is then carried out by HPLC or gas chromatography (see Measurement of Organic Atmospheric Pollutants).

5.3.4. ***Optical Methods of Remote Measurement***

Whereas the methods so far described enable atmospheric pollution to be measured at a single location, remote methods of optical measurement usually enable integrating measurements to be carried out with light beams up to several kilometers in length. They exploit the absorption properties of atmospheric gases in the UV, visible, or IR spectral regions, and are based on the Lambert – Beer law, which states that the measured extinction is proportional to the product of the path length and the concentration. If the wavelength of the radiation source and the detector in the measuring equipment can be varied, several components can be measured in parallel or in sequence with a single device.

Remote optical sensing methods thus enable measurements to be performed in areas to which access is difficult or impossible, or to trace diffusive emissions from large-area sources such as landfills or petrochemical plants with extended

piping systems and storage tanks.

The five most commonly used measuring systems — FTIR, DOAS, TDLAS, DAS-LIDAR (or DIAL), and COSPEC — are discussed below. Reviews can be found in [312], [313]; minimum requirements for type approval of instruments have been standardized [314].

5.3.4.1. *Fourier Transform Infrared Spectroscopy*

The Fourier transform infrared spectroscopy (FTIR) method is a true multicomponent system which simultaneously measures the spectra of all compounds present in the light beam that absorb in the IR range typically between 500 and 3500 cm^{-1}. The heart of the equipment is an interferometer, which produces interferograms from which the IR spectra are obtained by Fourier analysis [312]. In most applications close to ground level, artificial light sources are used, which are either at a distance of as much as several hundred meters from the spectrometer (bistatic arrangement), or which direct the light beam into the spectrometer by means of reflecting mirrors (monostatic arrangement). If white cells are used, measurements at almost point locations are also possible. A large number of organic components at concentrations of a few ppb can be measured in a light beam ca. 500 m in length. The FTIR method can thus be used as an “optical fence” for the effective monitoring of large-area sources of organic compounds such as petrochemical plants or waste dumps [315], [316]. If the light source and the spectrometer face towards each other and are mobile, gridlike surveys of large-area sources can be carried out [313]. Light paths of several hundred meters yield detection limits which are low enough for measurements in urban background locations [317]. Another important application is the monitoring of gaseous compounds contributing to climate forcing such as CH_4, N_2O, and CO_2 [318]. The FTIR method, its fields of application, and quality assurance have been described in a national standard [319] and in an upcoming CEN standard [320]

The sun can be used instead of an artificial light source, especially for measurements from aircraft and balloons. Integrated column concentrations of trace gases in the atmosphere (e.g., ozone) can be determined in this way from ground level, as well as pollutants present in high smoke plumes [312], [313]. If hot exhaust gases (e.g., from aircraft engines) are observed, the FTIR system can be used to detect the emission spectra of the thermally excited molecules without using a light source.

5.3.4.2. *Differential Optical Absorption Spectroscopy*

Differential optical absorption spectroscopy (DOAS) is probably the most widely used method of pollution monitoring on account of its comparative ease of operation. There are several manufacturers of commercial equipment [312]. It operates in the UV and visible spectral regions, usually with a high-pressure xenon lamp as light source. The light source and spectrometer can either be in the bimodal arrangement, as used in the FTIR method, or the light beam can be directed into the spectrometer by a reflecting mirror. By using beam lengths of up to 10 km, some harmful substances (e.g., HONO), can be measured at concentrations of < 100 ppt [313], [321]. However, this requires very good atmospheric visibility, as fog and rain, for example, attenuate the light beam so much that the beam length must be limited to <100 m for practical purposes [322]. The light is collected by a telescope and focused onto the slit of a diffraction spectrometer. A photomultiplier acts as detector and measures the differential absorption coefficients, which are a measure of the difference between the absorption I measured at the wavelength and the broad band background I_0. Because the light source has a broad bandwidth, a wide spectral range is available, allowing several characteristic lines of the trace gas to be measured.

The sequential measurement of several components is possible, as is the use of several spectrometers simultaneously, although the number of components that can be measured is appreciably smaller than is possible with FTIR. However, the DOAS system has very low detection limits, enabling unstable trace substances such as NO_3 (see Section Measurement of Unstable Trace Substances) to be measured. The DOAS system is used for measuring line sources (e.g., streets) and area sources (e.g., airports), but also for general air-pollution monitoring as a supplement or alternative to conventional measurement stations [313], [317]. The DOAS method has been standardized [323].

5.3.4.3. *Long-Path-Length Absorption Spectroscopy with Tunable Diode Lasers*

Tunable cooled diode lasers can be tuned specifically to the absorption bands of atmospheric pollutants of interest and can provide monochromatic, coherent, narrow light beams in the visible to IR range (3 – 30 μm) for use in absorption spectrometry (TDLAS); sensitivities are in the ppt range [324]. By using long path lengths in low-pressure white cells (a few millibar), it is possible to measure unstable trace substances that are important in air pollution chemistry (e.g., ·OH radicals) [325]. In open absorption paths, the detection limits increase to about 1 ppb, because of pressure broadening of the absorption bands. When compared to FTIR, TDLAS is superior in respect to sensitivity and selectivity. However, because of the narrow light beams of the laser, only one compound per laser can be measured. Multilaser arrays enable the measurement of several compounds [326].

TDLAS has found wide application as a research tool [324]. However, the relatively high capital costs, the need to cool the laser to 20 – 110 K, the difficult operation of the equipment, and the uneven quality of the laser have prevented routine application in pollution monitoring up to now, but improvements such as better white cells with paths lengths of up to 1 km and high-frequency modulation of the diode current are underway [326]. A simplified mobile absorption spectrometer in which the laser is replaced by a different light source in the infrared range is commercially available [327] and is used for monitoring large-area sources. However, it cannot achieve the low detection limits of laser systems.

5.3.4.4. *Differential Adsorption LIDAR*

If a laser beam is directed into the atmosphere without a reflector, part of the radiation is scattered by particles and air molecules, whereby a very small fraction is reflected in the direction of the laser source and can be detected by an adjacent telescope. If pulsed laser light is used and the time taken for the reflected light to return is measured, the distance of the back-scattering particles can be determined. This technique is known as LIDAR (light detection and ranging). If, in addition, the laser beam is tuned to the wavelength of an absorption band in the visible, UV, or IR range and compared

with a reference wavelength adjacent to the absorption band, it is possible to determine the spatial distribution of the pollution. This measuring technique is known as differential absorption LIDAR (DAS-LIDAR or DIAL) [312], [313]. The measuring system can be stationary or mobile (detection vehicle, aircraft), and has been used for large-area pollution measurements in urban regions [328], measurements of the vertical profile of pollutants such as ozone [328], large-area sources such as waste dumps and refineries [327], [328], loading facilities for petrochemical products [327], for monitoring combustion gas plumes [327], and for the remote measurement of elemental mercury emissions from chlor-alkali plants [329]. If the laser beam is periodically swung over a particular area or rotated in a circle, a two-dimensional picture of the pollution can be obtained in which point sources, for example, show up clearly as concentration peaks [313]. The remote monitoring of emissions from exhaust gas plumes is hindered by the fact that only the concentration of a pollutant is measured, and not other important parameters such as volume flow rate, temperature, or the oxygen content of the combustion gas.

Monitoring techniques using DAS-LIDAR have been standardized [330], and several instruments are used in the field [330], [329], [331]. However, DAS-LIDAR has not become widely used on a routine basis, probably because of high equipment costs and the difficulty in operating the laser, which affords highly trained personnel.

5.3.4.5. *Correlation Spectroscopy and Gas Filter Correlation Spectroscopy*

In correlation spectrometers, a spectral region of the undisturbed incident light is correlated with a prepared etched slit mask spectrum of the gas to be measured (COSPEC) [313] or with a reference cell which contains the gas to be measured (GASPEC) [312]. Both the slit mask spectrum and the reference cell rotate in front of the detector, so that the measured signal and the reference signal are detected alternately.

COSPEC passively measures the incident light, and determines the vertical concentration column of the components to be measured (SO_2 and NO_2). Both stationary and mobile operation (aircraft, detector vehicle) are possible, and commercial equipment is available.

The main applications are in studying atmospheric chemical reactions (e.g., conversion of NO to NO_2 in combustion gas plumes), and in the measurement of cross-border pollution from aircraft or detector vehicles [332].

5.3.4.6. *Significance of Remote Measurement Methods*

Remote measurement methods offer a number of advantages over conventional point-measurement technology:

1. Measurements at places and areas to which it is difficult or impossible to gain access (e.g., factory land, waste dumps, chimney stacks).
2. Continuous or quasi-continuous integrating measurement over an area (e.g., factory fence, factory land). This enables, for example, localized gas emissions from diffuse sources to be detected immediately, whereas single-point measuring equipment can often be at the “wrong” location. Moreover, integrating measurements provide a more representative picture than point measurements, for example in urban background locations, which should be representative for an area of several square kilometers.
3. Measurement of vertical profiles of air pollutants (e.g., O_3).
4. Measurement without physical contact (e.g., no spurious results caused by the sampling process itself), so that the measurement of highly reactive trace substances (e.g., $NO^{\cdot}_3$ radicals) is also possible.
5. Measurement of many pollutants simultaneously (FTIR), and measurement of substances that are very difficult to measure by conventional methods (FTIR, DOAS, TDLAS).

These advantages must be balanced against the disadvantages of high costs; operation difficulties, especially of the laser systems; high personnel requirement; the unacceptably high detection limits in many applications (especially FTIR and DIAL); and the difficulty in incorporating the remote measuring method into regulations for air pollution monitoring, which were not conceived for integrating measurements but for conventional point measurements. Some examples of this are listed below:

1. The incompleteness of the results obtained by some remote measurement methods in darkness or fog (e.g., COSPEC, DOAS) does not comply with the requirement for measurements to be representative of all times of the day (see Section Planning of Pollution Measurements).
2. For routine monitoring in some countries (e.g., Germany, the USA, EC Guidelines), the equivalence of measuring methods to reference methods, which are always based on point measurements, must be proved, and the uncertainty of the results must be demonstrated to fulfill given criteria (e.g., expected uncertainty of 25 %) [133]. In open areas, this is only approximately possible [312], but the application of absorption cells make traceability to a gas-based standard and the regular use of test gases for quality assurance possible [317].

As a result of these difficulties, remote monitoring methods are so far mostly confined to special and research applications, such as monitoring diffusive sources or ozone profiles. However, the standardization of several methods and their quality assurance as well as their type approval in association with continuing improvements to the methods may lead to wider practical use in the future.

5.3.4.7. *Measurement of Unstable Trace Substances*

The use of long light paths for remote measurement gives high sensitivity and lack of contact with the substance during “sampling”, thereby enabling important unstable trace substances in the atmosphere to be measured (see Section Significance of Remote Measurement Methods). Examples include $NO^{\cdot}_3$ and HNO_2 (DOAS) [333]; $OH^{\cdot}$ radical and H_2O_2 (TDLAS) [325], [334]; and HNO_2, N_2O_5, CH_2O, and organic intermediates (FTIR) [335]. Although remote measuring techniques do not involve contact with the substance, they can nevertheless lead to spurious results. Thus, in

addition to OH· radicals being present at low concentrations (< 1 ppt), unless special countermeasures are taken, laser light at 308 nm causes photolysis of ozone followed by reaction with water vapor, producing additional OH· radicals in the measurement path [325].

Conventional point measurement techniques are also used for this group of substances, e.g., gas chromatography for peroxyacetyl nitrate [336] and fluorescence measurements on H_2O_2 [337].

5.3.5. *Measurement of Organic Atmospheric Pollutants*

5.3.5.1. *Overview*

The main problem with the measurement of organic atmospheric pollutants is the large number of substances of this type. Several hundred individual substances are listed in emission registers and air quality management plans for densely populated areas. These have a very wide range of toxicological, chemical, and physical properties. TA Luft alone lists ca. 120 organic pollutants and 15 organic carcinogens with varying degrees of relevance to air pollution [140].

The large number of substances suggests that the high cost of measuring the individual substances could be met by summation measurements, e.g., of parameters such as the total content of organically bonded carbon (total C) in the atmosphere. This was the first route taken in monitoring atmospheric pollution.

However, it subsequently became clear that because the effects and concentrations of the various organic compounds were so variable, measurements of total C were not very useful. For example, a benzene concentration of 100 µg/m^3 in the atmosphere represents a considerable cancer risk [299], but the same concentration of *n*-hexane is considered harmless. This applies even more strongly to highly toxic compounds.

Total C measurements were therefore increasingly supplemented or replaced during the 1980s by single substance determinations of the relevant organic components.

This means that the analysis for organic compounds in the atmosphere is an exercise in “applied chromatography” (see ⟶ Basic Principles of Chromatography), as it is necessary to separate the complex mixture of organic compounds present. Highly sensitive detectors and mass spectrometers are available for a wide range of concentrations extending over ten orders of magnitude, i.e., from the mg/m^3 range (e.g., tetrachloroethene in close proximity to emitters) down to the fg/m^3 range (dioxins, furans). Chromatographic methods are therefore the methods of choice if the organic compounds are fairly stable both thermally and chemically. However, there are also special methods for a number of organic substances with reactive functional groups. Here, the physical properties or chemical reactions of the functional groups are utilized to detect the substances.

5.3.5.2. *Summation Methods (Total-C Measurements)*

The standard method [338] used to determine the total C content of the atmosphere consists of introducing the air sample directly into a flame ionization detector (FID). The hot hydrogen flame of the FID produces a ionization current in the presence of organic compounds, which is measured. The sensitivity (response factor) of FID is not the same for all organic compounds. Whereas the response factors of hydrocarbons lie close to unity relative to the calibration standard propane, this figure can greatly decrease for compounds with several heteroatoms (e.g., oxo compounds, halogenated hydrocarbons). Compounds of low volatility, largely associated with the aerosol, are detected incompletely or not at all. Therefore, the FID method underestimates the content of organic substance not consisting of high- to medium-volatility hydrocarbons.

Apart from total C determination, FID is an important detector with a wide range of applications in gas chromatography. As FID can be operated by continuously feeding the air sample, it is suitable for use in automated stations.

Even if results are difficult to interpret from the point of view of air pollution control, they are always of some significance when linked to the problems of increased ozone concentrations and to the detection of unusual pollutants in areas occupied by the petrochemical industry.

5.3.5.3. *Chromatographic Methods*

In the analysis of organic compounds in air gas chromatography (GC, see ⟶ Gas Chromatography) and high pressure liquid chromatography (HPLC, see ⟶ Liquid Chromatography) are widely used for separating the complex mixtures of substances. In gas chromatography high-resolution capillary columns with small cross sections (ca. 0.2 – 0.3 mm) and lengths of 30 – 60 m are now used almost exclusively (HRGC).

After separation on the column, the compounds are detected individually by various detectors, including FID, electron capture detectors (ECD, specifically for electrophilic substituents such as halogens), photoionization detectors (PID, which are very sensitive to aromatic hydrocarbons and other π-electron systems), and thermoionic detectors (NPD, specifically for nitrogen and phosphorus compounds). The HPLC system incorporates special flow-through detectors, similar to the flow-through cells of a UV spectrometer.

An especially powerful method is to use a mass spectrometer as the detector. Knowledge of the mass spectrum of an organic compound often enables it to be identified with certainty, especially in unknown mixtures of substances. Qualitative knowledge of the retention time from chromatograms obtained with conventional detectors, is generally only useful for mixtures whose composition is largely known.

When high-resolution gas chromatography is combined with mass spectrometry (HRGC – MS), the specific detection of individual components using mass fragmentograms is combined with high detection sensitivity, so that difficult analyses such as the determination of polyhalogenated dibenzodioxins and dibenzofurans in the atmosphere then become possible.

Analysis is preceded by sampling, for which various techniques are used, as organic compounds can differ so widely with respect to volatility, polarity, and concentration range.

The choice of sampling method is mainly determined by volatility. It is therefore useful to divide the analytical techniques into those for volatile and those for low-volatility compounds, methods for the latter being subdivided into those based on concentration measurement and those based on deposition measurement.

5.3.5.3.1. Chromatographic Methods for Volatile Organic Compounds (VOCs)

In spite of the high sensitivity of gas chromatographic detectors, direct measurement of VOC in the air is not possible without prior concentration on sorbents during sampling or in traps prior to analysis (with the exception of methane), as detection limits in the range ng/m^3 to µg/m^3 must be achieved. Sampling and preconcentration can be performed either by actively pumping an air stream through tubes or traps filled with sorbents or by passive sampling. The collected VOCs are then desorbed thermally or with solvents, and the resulting gas streams or solutions are injected into a gas chromatograph. The preconcentration step with subsequent thermal desorption can be part of the chromatographic system, so that air samples (e.g., from cylinders) can be introduced directly.

Both manual and automated methods are widely used, depending on the compounds to be analyzed and the time resolution and detection limits to be achieved. An overview of the usual methods for active pumped sampling and subsequent chromatographic analyses is given in Table 11. Two of the examples presented in Table 11 have been standardized by CEN as reference methods for benzene measurements: active pumping with adsorption on organic polymers followed by thermal desorption [339] and active pumping followed by adsorption on charcoal with subsequent desorption by solvents (CS_2) [340].

Table 11. Widely used chromatographic methods of determining organic pollutants (pumped sampling)

Substance group	Concentration range	Sampling, treatment	Final analysis	Refs.
Low-boiling hydrocarbons, volatile halogenated hydrocarbons	ng/m^3 – µg/m^3	evacuated passivated stainless steel cylinders (also for measurement of background air); samples fed via gas loops; cold trapping; thermal desorption	PID GC/FID/ECD	[346], [349]
Organic compounds, C_6 – C_{30}, *bp* range 60 – 350 °C	µg/m^3	adsorption on activated carbon; desorption with CS_2 or other solvents	capillary GC/FID	[350], [351], [353], [340]
Organic compounds, *bp* range 20 – 300 °C	ng/m^3 – µg/m^3	adsorption on organic polymers (e.g., Tenax) or carbon molecular sieve (Carbopack), thermal desorption with cold trapping before capillary column or solvent extraction	capillary GC/FID/ECD/MS	[341], [347], [348], [339]
Modification for low-boiling substances (< – 120 °C)	ng/m^3 – µg/m^3	adsorption on cooled polymers (e.g., Thermogradient tube); cooling to – 120 °C; use of Carbopack	capillary GC/FID/ECD/MS	[343]
High-boiling organic substances partly bonded to particles (e.g., PAH, PCB, PCDD/PCDF); high sample volume	fg/m^3 – ng/m^3	sampling on filters (e.g., small filter equipment) or high volume sampler with attached polyurethane cartridge for the gaseous fraction; solvent desorption of filter and sometimes of polyurethane; various purification and other treatment stages; sublimation of PAH	capillary GC – GCMS (PCDD/PCDF); capillary GC – FID or MS (PAH); HPLC fluorescence detector (PAH)	[385], [382], [365], [366], [367, 369]
High-boiling organic compounds, e.g., CHC, PCDD, PCDF, PBDD, PBDF; low sample volume	fg/m^3 – ng/m^3	adsorption on organic polymers (e.g., polyurethane foam cylinders) with filters (e.g., glass fibers) or inorganic adsorption (e.g., silica gel); extraction with solvents; various purification and other treatment steps (e.g., multicolumn	HRGC/ECD (CHC) capillary GC-GCMS (PCDD, PCDF)	[341], [373], [368], [369]

		chromatography); formation of derivatives of chlorophenols		
High-boiling organic compounds bonded to particles, e.g., components of organic aerosols; deposition samples	ng/m^3 (aerosol: ng/g – µg/g) (pg – ng)/m^2 d^{-1}	Collection of the aerosol on glass fiber filters (e.g., high- or low-volume samplers) or collection of dust on standard surfaces; extraction with solvents; various purification and other treatment steps	HRGC/MS (for PCDD/F) HPLC (for PAH)	[382], [374], [375], [383]

The most common adsorbents used for sampling with subsequent thermal desorption are organic polymers such as Tenax [poly(diphenyl oxide)] and Chromosorb (styrene/divinylbenzene copolymer) or carbonaceous sorbents such as Carbotrap (graphitized carbon), carbonized molecular sieves, and charcoals. A description of sorbents and guidance on sorbent selection and use is given in [348]. If compounds with a wide range of volatility have to be analyzed, the sorbents can be used in series. Care must be taken that no break through of VOCs occurs during sampling. This can be achieved by limiting the sampling volumes to safe levels [348].

This sampling procedure is appropriate for a wide range of VOCs, including hydrocarbons, halogenated hydrocarbons, esters, ketones, and alcohols. Very low boiling compounds may only be partially retained. However, the use of cooled carbon molecular sieves, which have a higher adsorption power than Tenax, enables the sampling of compounds with *bp* < 40 °C [347], [343] such as Freons.

The sampling of VOCs on solid adsorbents followed by thermal desorption and gas chromatography has been automated. Suitable process chromatographs are available from several suppliers (e.g. Chrompack, Airmotec, Siemens, Horiba, and Air Instruments), which can be run in automated measuring networks and which thus enable the quasicontinuous monitoring of VOC. The instruments have FID or PID detectors and are mainly used for the determination of volatile hydrocarbons such as benzene, toluene, and xylene (BTX aromatics). Several automated instruments have been tested and approved by the German authorities [357], [358]. Examples of automated instruments for the monitoring of benzene and the procedure for type approval have been standardized by CEN as reference method [177]. Remote measuring methods for organic compounds, which can also be applied for continuous monitoring, are described in Section Optical Methods of Remote Measurement.

The solid adsorbent is contained in tubes that can be sealed at both ends, and through which a definite amount of air is drawn by a pump (ca. 0.1 – 1 L). Depending on the flow rate and quantity of air, sampling times can be varied from a few minutes to a few hours.

For analysis, the tubes are connected to the sampling system of a gas chromatograph, and the adsorbed compounds are thermally desorbed in a stream of inert carrier gas. Direct feeding to the capillary column is not possible, as the gas volume of several milliliters would lead to loss of the separation effect of the capillary. Intermediate condensation in the gas chromatograph (cold trapping) is therefore carried out, followed by controlled thermal desorption to feed the capillary separation column (cryofocusing). Detection is performed by FID (hydrocarbons), ECD (halogenated hydrocarbons), or mass spectrometer.

This method is also suitable for the analysis of ground air [354], e.g., over abandoned polluted areas and waste dumps.

As an alternative to thermal desorption, solvents such as toluene, carbon disulfide, and pentane [350], [351] can be used, followed by injection of the solution into the gas chromatograph. This method enables thermally labile halogenated hydrocarbons such as dibromoethane to be analyzed [355]. The measurement of organic soil pollutants by the solvent desorption technique has also been described [352].

In the United States, active sampling using specially passivated stainless steel canisters is more widely used than collection on solid adsorbents. This method has been standardized by the EPA [346]. Containers with a capacity of ca. 1 – 15 L are evacuated, taken to the test site, and filled with the air to be analyzed via a critical nozzle or an active pump in the sampling system. A disadvantage of using a pump is that it must be attached to the pressure side of the canister, so that there is a danger of contaminating the sample. However, some problems associated with the use of adsorbents are avoided, such as impurities leading to high blank figures and the decomposition of substances being measured. The volume flow rate during filling of the canister can be adjusted to such low values by means of flow regulators that sampling times of up to 24 h are possible. If the containers are at subatmospheric pressure before analysis, they are brought to atmospheric pressure with high-purity nitrogen, and a definite volume of air, e.g., 100 – 500 cm^3 is then drawn from the container into a gas sample loop by a pump. Moisture in the air can be removed by passing the sample through a dryer (risk of absorption of polar compounds). The substances being measured are then collected in a cold trap and released in a controlled manner as in the thermodesorption method described above, and gas chromatography is then performed.

If stainless steel containers with a blank value of zero are used, this method is also suitable for measuring background concentrations of Freons in the ppt range [346]. Terpenes and isoprene can also be measured in this way [356].

Sampling can also be carried out using bags made of Tedlar or Teflon. However, there is a considerable risk of contamination associated with this system, which is therefore mainly used for analysis at higher concentrations, e.g., in gases from waste dumps [345]. Polar compounds are partially adsorbed on the walls of the bag.

Special gas mice can also be used very successfully for sampling volatile $C_2 – C_9$ hydrocarbons. These are sealed with septums [344]. Some of the collected air is removed with a gas-tight syringe, fed into a gas-sample loop, and cryofocused [344].

All the sampling techniques described above are particularly suitable for measuring hydrocarbons and halogenated hydrocarbons. For the analysis of strongly polar compounds such as alcohols or ketones, the suitability of the methods must be tested in each case.

Solid adsorbents such as Tenax, charcoal, or Chromosorb in specially designed tubes or badges can also be applied for passive (diffusive) sampling of VOCs (see Section Screening Measurements). The great advantage of passive samplers is their easy and cheap handling in the field without the need for access to electricity. They are simply exposed for one or more weeks. After transfer to the laboratory, the samplers can be thermally desorbed [359] or, in the case of charcoal as adsorbent, desorbed with solvents like CS_2 [360]. Subsequently, the samples are analyzed by gas chromatography as described above for active sampling. Passive samplers are commercially available (e.g., Perkin Elmer or Chrompack with thermal desorption, Dräger with solvent desorption) and widely applied in ambient air for the determination of aromatic hydrocarbons such as benzene, toluene, and xylene (BTX) [361], [362]. Comparative measurements with active and passive sampling in the field have shown overall uncertainties of 15 – 25 % for diffusive samplers [363]. In combination with their easy handling, this makes them ideally suited for indicative measurements.

5.3.5.3.2. Chromatographic Methods for Low-Volatility Organic Compounds

Concentration Measurements. The difficulties in analyzing and sampling compounds of this class are due not only to their low concentrations (from a few ng/m^3 to the fg/m^3 range) but also to the fact that low-volatility organic compounds can exist in the atmosphere both bonded to particles and in gaseous form. In sampling, several cubic meters of air must be concentrated, so that if only the particles are collected by the sampling procedure, “blow-off” effects from the filters can be produced by the air flow being sampled [364].

This applies especially to the sampling of semivolatile compounds with vapor pressures above 10^{-8} kPa [365] such as polycyclic aromatic hydrocarbons (PAH) with three or four rings, whereas compounds with vapor pressures below 10^{-9} kPa, such as benzo[*a*]pyrene, can be often sampled satisfactorily by particle collection on filters [370], [366]. However, at ambient air temperatures above 30 °C, 20 % of benzo[*a*]pyrene and perylene passed through the filter [371].

The equipment used for sampling compounds with $bp \leq 500$ °C (e.g., polychlorinated biphenyls; hexachlorohexane; polyhalogenated dibenzodioxins and furans, PAH) therefore includes filters (usually of glass fiber) for collecting particles, followed by equipment to adsorb gases and other components that pass through the filter.

For the collection of particles in the first stage of the sampling train, conventional high- [376], medium- [368], or low-volume samplers [369] are used, which are standardized for SPM measurements with the correct sampling rate. This is necessary to avoid particle size discrimination. The second stage, which can be integrated into the sampling head [368], [369], consists of an adsorption unit, usually a polyurethane foam plug [368], [369] or an organic polymer such as XAD/2 (Amberlite) [372], in which all compounds passing through or blown off the filter are trapped. For the analysis of PAH, a procedure using high-quality samplers has been standardized by ISO [365]; standard procedures for the determination of PCDD/F and PCB by VDI/DIN are available [367-369].

Before sampling, standards (e.g., ^{13}C-labeled congeners) can be added to determine whether losses occur during the sampling operation.

After sampling, both the filter and the adsorbent are extracted, and further ^{13}C-labeled standards are added for calibration purposes. Workup and chromatographic cleaning of the extracts are then carried out prior to analysis by high-resolution gas chromatography coupled with mass spectrometry (GC/MS; PXDD/F), or using detectors (ECD, FID) with spot checking by GC/MS. Labeled standards are added before or immediately after sampling for quantification purposes.

High pressure liquid chromatography (HPLC) can be used as an alternative to HRGC, especially for the analysis of PAH, with detection by fluorescence detectors [366] or UV detectors. PAH derivatives with nitro and oxo groups are determined by HRGC [381].

Examples of these procedures are listed in Table 11.

These analytical techniques can be used to determine both brominated and mixed halogenated PXDD/F. The analytical problem is not only the large number of possible congeners (44 different homologue groups with 5020 single congeners) but also the lack of standard compounds for calibration. Therefore, only a few approximate analyses for PXDD/F in air have been undertaken so far [377], [378].

Very little information on the uncertainty and comparability in the measurement of pollution by PXDD/F have so far been published. In cooperative tests between four laboratories in 1989 [373], the experimental results (expressed as toxicity equivalents) showed standard deviations of 16 % in the first series of measurements and 23 % in the second.

Deposition Measurements. As ingestion in food accounts for most of the daily dose of PXDD/F or PCB absorbed by the general population, it is more important when studying the effects of low-volatility chlorinated compounds to measure their transfer into the food chain (e.g., by deposition on surfaces) than to measure their concentration in the atmosphere.

As with deposition measurements in general, wet deposition (rain, fog, snow), dry deposition, and total (bulk) deposition must be measured. Bulk deposition is measured with standardized dust deposition measurement apparatus (e.g.,

Bergerhoff method, see Section Measurement of Total (Bulk) Deposition) that has been simply modified (e.g., by shading from strong light). Some serious measurement problems (e.g., the resuspension of already precipitated particles, evaporation, and possible photolytic decomposition) have not been systematically researched, so that results are of an approximate character. Standardized methods for the measurement of bulk deposition of PCDD/F and PAH have been developed [374], [375], [379].

Bulk deposition of PCB has been determined in an analogous manner [384].

Wet deposition of PAH and chlorinated compounds such as PCB [386] or PCDD/F [387] has been investigated by using special rain and fog collectors, in connection with the transport of these compounds into relatively unpolluted areas.

5.3.5.4. *Determination of Organic Compounds with Functional Groups*

Organic compounds with functional groups (e.g., aldehydes and phenols) are difficult to analyze by chromatography because of their polarity, unless they are derivatized. However, the physical properties of the functional groups can often be utilized for detection by optical methods, such as infrared absorption or differential optical absorption spectrometry (Section Optical Methods of Remote Measurement). The chemical reactivity of functional groups can be used in reactions to form dyes, which are then determined photometrically, or derivatives are produced for chromatographic analysis.

Thus, aldehydes react readily and specifically with amines to form hydrazones. At concentrations of > 4 µg/m^3, formaldehyde can be determined by the color produced in the sulfite – *para*-rosaniline reaction followed by photometric measurement [388].

Reaction with 2,4-dinitrophenylhydrazine to form the hydrazone, followed by HPLC separation, is more sensitive [389], [390]. This method can also be used to determine higher aldehydes and ketones [390], and can be automated [390].

Similarly, phenol and the cresols react with *p*-nitroaniline in dilute NaOH to give azo dyes which can be determined photometrically [391]. In a method used for measuring pollution in Berlin in 1989, solid-phase extraction from the NaOH solution was followed by HPLC.

The alkylnitrosamine compounds present more serious problems of pollution measurement. There is in principle a gas chromatographic method based on a nitrosamine-specific detector (TEA) and concentration of the alkylnitrosamines on Tenax tubes followed by thermal desorption [392]. However, at the relevant low atmospheric concentrations (a few ng/m^3), there is considerable risk of the unwanted formation of nitrosamines from amines and NO_x on the concentration or separation columns.

Future developments in the analysis of organic atmospheric pollutants will mainly be directed towards inexpensive screening methods, so that the costly analysis of single substances can be concentrated on the most important cases and air pollution monitoring can be kept within economically acceptable limits.

5.3.6. ***Olfactory Methods***

Olfactory methods are used in pollution monitoring to enable the nuisance caused by odors to be objectively assessed in terms of their frequency, intensity, duration, and/or hedonic effects [395], [396]. Fields of application are licensing procedures for installations emitting odorous compounds, cause analysis in the case of complaints, estimation of odor emissions, and calibration of dispersion models [397].

In practice, there are two methods to assess the odor impact in terms of odor frequency:

1. Measurement of the emission concentration (number of odor units) with an olfactometer (see Chap. Emission Measurements), followed by diffusion modeling [398], [399]
2. Odor determination by field inspections with panelists, either by grid measurements or by plume measurements [397]

Method (1) combines olfactometric emission measurements with diffusion modeling and cannot strictly be regarded as pollution measurement. In the method (2), measurements on site are carried out by panelists. In both measurements, the human nose is used as the detector. However, the direct relevance of this detector to the effect to be assessed must be balanced against its considerably lower precision compared with physicochemical methods of pollution measurement. On the other hand, direct measurements of main odor carriers by physicochemical methods are infeasible in most cases due to the complex mixture of odorants, although gas chromatographs equipped with olfactory detection ports parallel to normal detectors can be used to identify the main odor carriers [400].

Field inspections by grid measurements are carried out in accordance with precisely laid down measurement plans by a group of panelists, who record at the locations and times specified whether odors are recognizable and can be identified as characteristic for the source to be studied (an odor event). From the number of odor events during the measurement time, the number of odor hours per year (odor impact) can be determined, and these give a measure of the significance of the odor problem [401]. The locations to be tested are usually arranged in a regular grid of 250 × 250 m in the surroundings of one or several odor source(s) or in an area to be assessed; the sampling times are chosen to be representative for the measurement period (12 or 6 months). The measurement plan thus corresponds closely to the grid arrangement of monitoring stations outlined in Section Measurement Networks (General Air Pollution Monitoring). Field inspections of odors are particularly suited for license procedures and have been standardized [402]. In addition to the frequency of odor events, the intensity of odors and their hedonic properties such as “pleasant”, “unpleasant”, or in very rare cases “nauseating” can be taken into account [401], and standardized methods to do so are in preparation [403]. Questionnaires can be used to link the measured frequency of odor events with the nuisance percieved by residents in an area [404].

German Antipollution Laws do not contain scales of judgment for assessing the significance of odor problems, but this gap is being filled by administrative regulations prepared by the Länder [405], [401].

Field inspections by plume measurements [406], [407] examine the odor plume of a source or group of sources, depending on the current emissions and dispersion conditions. Typically, three cross sections are established perpendicular to the axis of the plume, and each cross section consists of at least five measurement points at which the frequency of odor events and, where appropriate, also the odor intensity and hedonic properties can be assessed by the test panel. Plume measurements are performed to identify emitters and, in combination with dispersion modeling [399], they can be used to estimate the source strength of emitters. If the source strength is known, for example, by emission measurements, plume measurements can be applied the other way round to validate and calibrate dispersion models.

5.3.7. *Screening Measurements*

Simplified measuring methods, possibly with a higher measurement uncertainty compared to more sophisticated methods described above, are used for instance for preliminary investigations (screening). Examples include diffusive samplers, detector tubes, biological methods, and sensors.

In the past, such methods were mainly used for the monitoring of work environments (personal sampling) and air quality in buildings, and sometimes for epidemiological investigations [408]. Development and implementation of the new European Air Quality directives [132-135] led to a considerable need for relatively inexpensive and comparably simple methods of ambient air measurements. Three CEN standards were developed for diffusive sampling where general and specific requirements were defined [409], [410]. The third part of this standard provides guidance for selection, use, and maintenance of such methods [411].

The CEN standards define a diffusive sampler as “a device which is capable of taking samples of gases or vapors from the atmosphere at a rate controlled by a physical process such as gaseous diffusion through a static air layer or a porous material and/or permeation through a membrane, but which does not involve the active movement of air through the device”.

In diffusive samplers, the substance to be determined is collected for example, on adsorption media like charcoal, synthetic organic material, or impregnated filters and meshes. This contrasts with active sampling processes in which air is drawn through a sampling medium by a pump. After a certain exposure time, the collected substance is determined analytically, and its original concentration is calculated based on the relevant physical laws (e.g., of diffusion), taking into account the substance-specific diffusion coefficient, collection time and the geometrical parameters of the sampler.

At present, diffusive samplers — especially for nitrogen dioxide and benzene — are widely used under the European Air Quality Directives, e.g., for preliminary assessment, indicative and screening measurements, network design and optimization, assessment in the vicinity of point sources (traffic, industry), and for assessments in ecosystems [411], [412], [413], [414], [161]. An overview on ambient air measurement by diffusive sampling is given in [415].

Passive collectors are very cheap compared with active measurement devices, a further advantage being that no energy source is required. Disadvantages may be founded on nonideal behavior of the samplers and the dependence on meteorological parameters such as temperature, humidity, and wind speed. In such cases, validated uptake rates must be determined by on-site calibrations, e.g., by parallel measurements with a reference method [161].

Detector tubes are used for sampling and rapid analysis of gases [416]. A hand pump or automatic sampling device is used to draw a given volume of air through a glass tube containing a specific reagent supported on a carrier. The reagent changes color in a characteristic manner depending on the concentration of the substance tested in the air. Detector tubes are mainly used for workplace monitoring or as rapid measurement methods in accidents. They are not used for routine pollution measurements because the detection limits are normally too high and selectivity is poor. Detector tubes are available for many substances over a wide range of concentrations.

Two biological methods are routinely used in pollution monitoring. In the standard lichen exposure method [418], the death rate of the lichen is determined over an exposure time of 300 d. In another method, a species of rye grass is exposed for 28 ± 1 d [419], and the growth of the grass is determined. Both methods enable the general effect of pollution to be determined.

Further development can be expected in the field of sensors which determine chemical states or parameters [420]. They often have the disadvantage of unacceptably high detection limits, poor selectivity and stability, drifting phenomena, and sensitivity to environmental conditions such as temperature. Sensors are already used in higher concentration ranges where great accuracy is not required (workplace monitoring, warning equipment, leak tracing).

6. Emission Measurements

Klaus Lützke

6.1. Introduction

To protect the environment, air-polluting emissions must be limited using state-of-the-art technology. Here, the word emissions is used in the legal sense, in accordance with § 3 Section 3 of the Federal Antipollution Law (BImSchG) [421]. Emissions can pass into the atmosphere in exhaust gases or waste air from fixed sources, such as chimney stacks. However, they can also be produced diffusely, e.g., from openings in buildings or waste-storage areas. Emissions are usually expressed as mass concentrations, but also as mass flow rates or mass ratios (mass of emitted material per unit mass of substance produced or processed). Atmospheric impurities are changes to the natural composition of the air due to smoke, soot, dust, gases, aerosols, vapors, or odoriferous substances (odoriphores). Methods for determining

emissions comprise both manual methods of measuring spot samples and continuous measurement techniques. Depending on the components measured and the measurement requirements, emission concentrations can be from the g/m^3 range down to the trace range (pg/m^3). As environmental protection standards have become stricter, new measurement methods have been developed with lower limits of detection. The demand for continuously operating measurement equipment has greatly increased. The methods described here therefore represent only an overview of the present state of measurement technology.

6.2. Objectives and Planning of Measurements

The definition of objectives must specify the quantities to be determined, the boundary conditions, and the required accuracy of the results. There can be many different reasons for determining emissions. Typical objectives include: monitoring compliance with emission limit values; determination of agreed guaranteed figures for production plants and exhaust gas purification plants (acceptance measurements); calibration of continuously recording emission measurement equipment; testing the functioning of continuously recording emission measurement equipment; emission control monitoring fitness for use; analysis of the causes of noncompliance with guaranteed values or emission limit values; determination of changes in the emissions from a plant after process changes, operational disturbances, or design modifications.

Pollution control regulations require that compliance of plants with emission limit values be monitored. In Germany, the main regulations are the Federal Antipollution Law (BImSchG) [421], TA Luft [422], 13th BImSchV [423], 17th BImSchV [424], and 2nd BImSchV [425] (see Chap. Laws and Technical Regulations). In the licensing procedure, the requirements included in the individual regulations form part of the conditions and supplementary provisions under which a plant must be operated (requirements of the authorities). The rules concerning the monitoring of performance characteristics (proof of guarantee) of items of plant and gas purification installations are civil law agreements. The monitoring of compliance with emission limit values is already regulated by the Federal Antipollution Law. According to this, the authorities can order that, in the case of licensable plants [426], measurements should be carried out after bringing into service, after a significant change, or after certain periods of time. As well as random sample measurements (spot measurements), continuous measurement and recording of certain emissions may be required.

In measurement procedures, the measurement plan is of great importance. Measurements for determining plant emissions should be carried out such that the results correctly represent these emissions and are comparable to similar plants and operating conditions [422]. Before the measurement plan is produced, the objectives of the measurements must be exactly defined [427]. These objectives are usually based on licensing information, official regulations, or contractual documents (acceptance measurements). Alternatively, guidance can be obtained from relevant administrative regulations or VDI Guidelines. According to these, the necessary prior knowledge of the plant under investigation can be used, e.g., technical data about the plant, information about operational behavior, materials used, positions of the measurement points, etc. This is supplemented by knowledge about the measurement methods to be used, the personnel plan, and the time period. In the measurement plan, the following must be specified:

1. Where will the measurements be carried out?
2. What must be measured?
3. How are the measurements made?
4. What accuracy is required?
5. How will the results be determined?
6. Who will carry out the investigations?
7. When will the measurements by carried out?

VDI 2448 describes the planning of spot sampling measurements of stationary source emissions [427]. The measurement plan should be produced at an early stage. For example, the planning of acceptance measurements must be started at the planning stage of the plant. The type of measurements to be carried out, the arrangement of measuring ports, and the equipment for the measurement points must be considered and fixed. If this work is done at a later stage, the installation costs are often higher. A detailed plan is especially important if the equipping of measurement points will be impractical at a later stage, as in the case of coated exhaust gas ducting, or if the measurement points are no longer accessible or are unsuitable. In planning, the accessibility and the minimum requirements that apply to exhaust gas ducting must be considered. VDI 2066, Sheet 1 gives advice on the minimum length required for the exhaust gas ducting upstream and downstream of the measurement point [428]. For measurements at existing plants, the measurement plan must conform with plant conditions. The arrangement of measurement points then cannot always be freely chosen. In every case, it must be judged whether a measurement can be regarded as representative. If it is not, modifications to the measurement technique to improve its accuracy must be considered.

6.3. Requirements for Measurement Techniques and Measurement Stations

Emission measurements must be carried out using state-of-the-art techniques and equipment. TA Luft prescribes that emission measurements must be carried out in conformity with certain guidelines and standards of the Commission for Atmospheric Pollution in the VDI and DIN. Alternative or supplementary measurement methods are permitted, especially if they are accepted by the Federal Environmental Ministry with agreement with the highest Land authorities. The guidelines by the Commission for Atmospheric Pollution in the VDI and DIN describe the established state of the art in the measurement field.

6.3.1. *Quality of Measurement Methods*

The quality of the measurement method must meet the requirements of the measurement task. To specify measurement performance, quantities characteristic of the measurement method are used, such as detection limits and determination limits as defined in VDI 2449, Sheets 1 and 2 [429], [430]:

Detection limits and *determination limits* must lie significantly below the lower emission limit. In general, the detection limit

should be less than one-tenth of the lower emission limit. Where there are no emission limits, but compliance with other constraints must be monitored, requirements are analogous.

The *measurement uncertainty* can be determined from the reproducibility found in duplicated determinations. The reproducibility of a measurement method is determined from a series of simultaneous determinations using two complete measurement procedures. The reproducibility can be based on the mean value of the sample of measured values or on classes of measured values. Thus, the standard deviation of the measurement process can be estimated from the number of pairs of measured values and the concentration of the substance.

The *selectivity* of the measurement method chosen must be sufficiently high with respect to other substances present in the exhaust gas, i.e., the cross-sensitivity must be low.

If continuously recording measurement methods are used, other parameters are important, e.g., linearity of the measurement signal, dead time, rise time, drifting of zero point and sensitivity, and setting-up times. The measurement method must cover the expected range of values. Similar considerations apply to the choice of methods for the measurement of reference quantities (O_2 content) and the state quantities temperature, humidity, and pressure.

6.3.2. *Choice and Equipment of Measurement Stations*

“Measurement stations should be of adequate size, easily accessible, and so designed and selected that technically problem-free emission measurements that correctly represent the emissions from a plant can be carried out” [422].

Measurement and sampling stations must be included at the planning stage of new plants. With existing plants, the requirements for measurement stations should be considered to enable the necessary modifications to be carried out and/or equipment to be installed during planned shut-downs. For all measurement stations, the following are fundamental requirements:

The association of the measurement station with the emission source must be indicated by unambiguous labeling. For this, the source numbers used in the description of the emissions or the company source numbers can be used. It should also be possible to a make an assignment to the relevant part of the plant or operation.

Flow into the measurement line should be as smooth and undisturbed as possible. Recommendations for the measurement of dust in flowing gases can be found in VDI 2066, Sheet 1 (dust measurements). The flow properties in the exhaust gas duct can be affected by merging gas flows, changes in direction, changes in cross section, inserted items of equipment, and valves. To ensure a flow which is as undisturbed as possible, the measurement/sampling point should be in a straight section of the exhaust gas duct with a constant size and shape. VDI 2066 specifies uninterrupted inlet and outlet pipes whose length is each at least three times the hydraulic cross section. To prevent sedimentation (e.g., when taking measurements in the unpurified exhaust gas prior to the dust filter), the measuring point for the determination of particulate emissions should if possible be located in a vertical part of the ducting. The sampling points should be so arranged that grid-based measurements can be made for determining both dust emissions and emissions in gaseous form.

The size of the measurement openings is determined by the type of measurement equipment and sampling probes. The number of openings depends on the size and shape of the cross section under investigation. The arrangement, number, and dimensions of openings usually used for dust measurement has also been found to be suitable for measuring gaseous components where measurement grids are required. A good solution consists of large circular openings with closable gas-tight lids which can be modified to suit the measurement task. This possibility of modifying the lid at a later stage is especially important if it is not possible to modify the ducting under investigation (e.g., because of the presence of a rubber lining for protection against acid).

The operating platforms for sampling and measurement must be sufficiently large to accommodate the sampling probes, sampling equipment, and associated measurement apparatus. Access to measurement stations must be provided in accordance with the relevant regulations. There must be no extraneous emission sources (e.g., bursting disks, safety valves) in the operating area of the measurement station. The measurement station must at least be provided with protection from rain and weather if the operating platforms are in the open. Adequate, correctly sized, and fused electrical supply points must be installed at the measurement station. Depending on the type of measurement, compressed air and water supply points may also be required.

6.4. Requirements for Continuous Measurement and Associated Computer Systems

For a number of licensable plants, systems for continuously monitoring emissions are legally required. In addition, owners of industrial plants in their own interest may carry out continuous monitoring of emissions to show that emission limit values are being complied with, e.g., if local residents complain about plant emissions. The regulation on power-station emissions (13. BImSchV) states that power stations must be provided with equipment for continuously monitoring emissions of dust, carbon monoxide, nitrogen oxides, and sulfur oxides, and that the results must be continuously and automatically evaluated [423]. The regulation covering incineration plants for waste and similar combustible materials (17. BImSchV) requires the continuous determination, recording, and evaluation of emissions of carbon monoxide, total dust, organic substances (as total carbon), gaseous inorganic chlorine compounds (as hydrogen chloride), gaseous inorganic fluorine compounds (as hydrogen fluoride), sulfur dioxide and sulfur trioxide (expressed as sulfur dioxide), and nitrogen monoxide and nitrogen dioxide (as nitrogen dioxide). Additionally, other exhaust gas parameters such as oxygen content, exhaust gas volume flow rate, and temperature must be determined and recorded [424].

For other licensable plants, TA Luft prescribes the conditions under which quantitatively significant emissions of dust and gaseous atmospheric pollutants must be continuously automatically measured and evaluated. The measuring equipment is specified in publications by the Federal Ministry responsible for antipollution. Testing for suitability, installation, calibration, and maintenance of measurement equipment are described in binding guidelines by the Environment Minister

in conjunction with the Länder so as to provide quality assurance and to ensure uniform federal practice in the monitoring of emissions.

6.4.1. *Minimum Legal Requirements*

A series of parameters, the so-called minimum requirements, ensure that continuously recording measurement equipment does not fall below a certain standard of performance [431]. These minimum requirements are from time to time reassessed in the light of the latest state of the art in measurement technology. They are subdivided into various general requirements, e.g., position of reference and zero points (live zero), recording range, and availability. Other requirements refer to measurement principles (e.g., photometry and radiometry), substance-specific properties such as dust content and smoke number, required degree of reproducibility, drift with time, and detection limits. Minimum requirements are also set for detection limits, availability, and the continuous measurement of reference values, e.g., oxygen content and waste gas volume flow rate. A separate guideline describes the requirements that apply to computers for the calculation of emissions [432].

There is a further guideline on the evaluation of continuous emission measurements on incineration plants (17. BImSchV) [433].

6.4.2. *Testing the Suitability of Continuous Measurement Methods and Evaluation Computers*

When testing for suitability, compliance with minimum requirements must be determined in laboratory tests and also in a long-term test lasting at least three months on an emitting plant. Standards of performance, but not measurement principles or any specific measurement equipment, are prescribed in the minimum requirements. Any kind of measuring equipment can be used, whatever its measurement principle, provided that it complies with the minimum requirements. Testing for suitability usually begins with the determination of characteristic performance figures in a laboratory test. After this, a long-term test under practical conditions is carried out on full-scale plants that require continuous monitoring of pollution emissions in accordance with legal and administrative regulations of the Federal Antipollution Law (13. and 17. BImSchV, TA Luft). The suitability test should be carried out with two similarly constructed measurement devices operating in parallel, with separate sampling, sample preparation, and data processing. The three-month test should be carried out under the severest known boundary conditions. If important minimum requirements are not complied with, the test is discontinued. The applicant can then carry out improvements, repairs, and modifications. Consideration must then be given to the question to what extent the changes to the measurement system make it necessary to retest any of the minimum requirements. On conclusion of the test for suitability, the testing institute produces a test report on the results. This is sent to the Federal Environmental Office and to the Länder Committee for Antipollution. If the Federal Ministry for the Environment, the relevant Land authorities, and the testing institutes agree that the overall judgment is positive, the certification of suitability is issued at the instigation of the Federal Ministry for the Environment in the general ministerial paper issued by the Federal Ministry [434], [435].

6.4.3. *Testing and Calibration of Measurement Equipment*

Quality assurance tests for continuously recording measurement methods can be divided into tests of internal equipment function, maintenance, annual functional verification, and calibration [436].

Internal equipment functions tested can include automatic changeover of mesh filters, automatic electrical balancing at given time intervals, or the regular functional checking of certain components (e.g., pumps, flowmeters).

Normally, the equipment must be maintained and tested at definite time intervals by the operator. This requires functional testing with calibration aids such as mesh filters and test gases.

For in-situ measurement equipment, the optical boundary surfaces must be cleaned, air filters must be cleaned or changed, and the zero point, the sensitivity, and data recording must be checked. In methods involving extractive sampling, the heater for the sampling system, the leak-tightness of the tubing, the sampling flow rate, and the condensate flow must be tested. The zero point and sensitivity must be tested and if necessary adjusted by using test gases.

For continuously recording measurement equipment, an annual functional test must be carried out on the complete measurement system, including sampling. In a general test of the state of maintenance, and, in the case of extractive sampling systems, a test of the leak-tightness of the measurement system, various testing activities are required. These can include: testing for soiling of the optical components or of the sampling system; determination of the changes with time of zero and reference points; determination of cross-sensitivity towards CO_2, CO, NO, NO_2, SO_2, water vapor, etc.; testing of the functioning of the equipment with test gases, test solutions, filters, or other equipment-specific standards with three or four values over the measured range. Also, specific equipment functions relevant to operational dependability are tested, e.g., constancy of sample stream offtake, duration of measurement cycle, metering and composition of reagents. The transfer of the measured figures to the data collection system must also be tested [437].

Continuously recording measuring equipment must be calibrated after a new plant has been put into service, after significant alterations, and at intervals of 3 – 5 a. Calibration is the determination of the relationship between the readings of the complete measuring equipment and the actual concentration of the substance present in the exhaust gas from the plant as determined by comparison measurements with a conventional analytical method [438], [439]. Checks on the maintenance and functioning of the system must be carried out beforehand. The figures determined simultaneously by the two methods are compared and statistically evaluated. To calibrate dust measurement devices, at least 12 – 15 comparative measurements are usually necessary [428], [440], these being carried out at a number of points arranged in a grid pattern covering the cross section of the ducting. This gives the grid-based analytical function.

With gas emission measurement equipment, there are two main procedures for determining the analytical function. In the first of these, which is analogous to that used in dust measurement, comparative measurements are carried out as grid analyses using a standard method suitable for a bulk phase, e.g., the H_2O_2 – thorine method for SO_2 determination (VDI

2462, Sheet 8). Sampling at the individual measurement points on the grid must be carried out at a rate proportional to the gas velocity and if possible, for various concentrations of the measured substance. This gives the grid-based analytical function. In the second method, a single point analysis is carried out. With continuously recording measurement methods using extractive sampling, ca 20 comparative measurements are carried out in the first stage, with the conventional method and the continuously recording measurement method being operated at adjacent sampling points. The statistical evaluation gives the single-point analytical function for sampling by both methods at the same place [438], [439]. The difference between the equipment-specific characteristic line and the single point and grid-based analytical function is shown schematically in Figure 6.

Figure 6. Calibration scheme for continuously recording emission measurement equipment

For many applications where the concentration distribution over the cross section is approximately uniform, this single-point analysis is sufficient. It includes the entire exhaust gas matrix and the variation of concentration with time. It might be thought that this procedure would also be valid for linear sampling by in-situ measuring equipment. However, even when the single-point analytical function is used, the evaluation requires additional grid measurements to verify that the concentration distribution is approximately uniform. In all cases where the concentration distribution is not uniform, this single-point analytical function must be supplemented by additional measurements to give a grid-based analytical function. Therefore, in a second stage, a correction factor must be obtained by means of approximate grid-based measurements, enabling the representativity of the measurement point to be improved. This stepwise procedure is recommended for calibration with single-point sampling. It has the advantage that the cost of the grid-based measurement can be reduced, because instead of using a conventional analytical method to determine the correction factors, a second continuous emission measurement apparatus is used whose results have previously been compared with those from the equipment being calibrated, which also operates by extractive sampling [438]. For the measuring equipment to be calibrated, the single-point analytical function has already been determined by a conventional analytical method, taking into account the complete exhaust gas matrix. Thus, these results can be transferred to the second emission measurement equipment. Grid-based measurements are then carried out. The results of the grid-based measurements, in combination with the single-point analytical function of the equipment to be calibrated, lead to a grid-based analytical function. The arrangement of sampling probes for determining the equipment-specific factor for a second recording method and the procedure for extending the single point analytical function to a grid-based analytical function are shown schematically in Figure 7.

Figure 7. Arrangement of sampling probes to determine the equipment-specific factor for a second continuously recording method, and a representation of the relationship between single point and grid-based analysis

6.5. Physical State Parameters, Reference Value Measurements, and Evaluation Computers

The physical quantities temperature and humidity, and the reference values oxygen content and carbon dioxide content must be determined at the same measurement point as the measured components within the length of ducting under investigation. The temperature of the exhaust gas and sampled gas and the pressure of the exhaust gas must be known to enable the mass concentration of the measured components under standard conditions (273 K, 0.1013 MPa) to be calculated. Figures for the mass concentration based on dry exhaust gas are generally also required, so that the moisture content of the exhaust gases must also be determined. The standard density of a gas mixture is found from the standard densities of the individual components and the quantitative composition. The standard density of each component is found by dividing the molecular weight by the molar volume in the standard state (DIN 1306 and 1871) [441], [442]. The oxygen, carbon dioxide, water vapor, and nitrogen contents enable the density of the exhaust gas (used in dynamic pressure measurements) to be calculated precisely. The oxygen content is an important reference value from which the measured concentrations can be calculated according to the equation

$$E_B = \frac{21 - O_B}{21 - O_M} \cdot E_M$$

where E_M = measured emission, E_B = emission based on the oxygen content, O_M = measured oxygen content, O_B = reference oxygen content.

6.5.1. *Temperature*

The exhaust gas temperatures at which emission measurements are carried out are generally in the range 50 – 400 °C, which can conveniently be measured by resistance thermometers or preferably by thermocouples. The relevant regulations on temperature measurement should be referred to [443-446]. The furnace temperature is now of great importance in refuse incineration plants, and must be monitored as prescribed in 17th BImSchV. This requires that the minimum temperature after the final addition of combustion air must be maintained at least between 850 or 1200 °C. These temperatures must be determined continuously, recorded, and evaluated. In this temperature range, only thermocouples have become established for long term use. As there is significant radiation in this temperature range, the thermocouples must be calibrated. Gas extraction pyrometers can measure gas temperature without radiative contribution.

The gas is sampled at a high rate by a pump and passed over a thermocouple. The thermocouple is covered with a protective tube to prevent errors due to thermal radiation. However, continuous long-term measurement is not possible at present [443].

Recording measuring equipment based on acoustic pyrometry has been marketed. This relies on the fact that the speed of sound in gases depends mainly on the temperature of the gas and only slightly on its composition.

6.5.2. *Moisture Content*

Several methods are in principle suitable for determining the moisture content in off-gases, including psychrometric difference measurement, the lithium halide dew point method, and condensation and adsorption methods. In off-gases, the H_2O content usually lies between 2 and 30 vol %, corresponding to a water dew point temperature of 20 – 70 °C. The determination of water content has hitherto been carried out by manual analysis, as continuous measurement was not technically feasible.

The regulation that deals with waste incineration plants (17. BImSchV) prescribes continuous measurement, recording, and evaluation. Initial investigations into the use of continuously operating LiCl moisture measurement equipment were carried out in an R & D project intended to formulate the minimum requirements that would apply to moisture measuring equipment. The LiCl sensor was replaced by an LiBr sensor to give good service availability [447]. Legally binding minimum requirements for the measurement of moisture content have existed since 1992 [448]. A multicomponent (HCl, SO_2, NO, CO) photometer which uses the single-beam, dual-frequency method, produced by Perkin – Elmer, has been approved for measurements on waste-incineration plants. It can also measure the H_2O content in the range 0 – 40 vol % [449]. Another recommended measuring device manufactured by Ultrakust operates as a back-scattering psychrometer [450]. This is suitable for the exhaust gases from furnaces and from incinerators for process and domestic refuse. The lowest measurement range during the test for suitability is 300 hPa water vapor partial pressure.

Other measuring equipment operating on the principle of a difference measurement on “dry” and “wet” zirconium oxide probes is currently being investigated for suitability.

6.5.3. *Carbon Dioxide Content*

During the 1970s oxygen content replaced the formerly used reference value CO_2 for standardizing measured emission concentrations. There are therefore no minimum requirements and suitability tests for CO_2 measurement equipment. Investigations have been carried out to determine to what extent CO_2 measurement could be used as a substitute reference value [447]. In the combustion of a single substance, the two reference values CO_2 and O_2 are interchangeable without appreciable error. However, in the combustion of mixtures, the discrepancies are significant because of differences in the maximum CO_2 content associated with the fuel. In random sample emission measurements the CO_2 content is usually also measured to enable the density of the exhaust gas to be better characterized. In principle, the Orsat method is suitable, but the measuring methods usually used are based on instruments such as the IR absorption photometer. Electrochemical methods are also used.

6.5.4. *Oxygen Content*

All discontinuous and continuous measure methods include a mean-value calculation followed by conversion to STP, and this is usually followed by a further conversion to a definite oxygen content. Because errors in O_2 determinations have an immediate impact on the results of emission measurements, minimum requirements apply. A number of types of measurement equipment have been approved [431, 434, 435, 449-451]. Sampling can be performed by extraction or in situ. In extractive sampling, the exhaust gas together with the other pollutants is passed through a cooling system, so that measurement results based on dry exhaust gas and 273 K are immediately obtained. Suitable measurement principles include the magnetodynamic method using a torsion balance (manufacturers: Bühler Mess- und Regeltechnik, Mannesmann/H.u.B., MC Products Analysentechnik, Maihak, Rosemount), the equal pressure or variable-pressure measuring method with an auxiliary gas (manufacturers: Maihak, Siemens), and the electrochemical method with a zirconium dioxide solid-state electrolyte (manufacturers: ASEA BBC, Enotec, Westinghouse Controlmatic, Yokogawa). Using the last-named measuring principle, the O_2 content is determined either as “wet” O_2 content directly in the exhaust gas duct, or as “dry” O_2 content by extractive sampling followed by cooling and condensate removal.

6.5.5. *Evaluation Computers*

To comply with the requirement to evaluate measured results continuously and automatically and to document them, the measured values from the recording equipment (dust, SO_2, CO, NO, etc.) are converted into the appropriate physical quantities based on the regression curves determined in the calibration, and are averaged over the reference time (usually 30 min) [432]. After converting to STP and reference oxygen content (e.g., 11 % O_2 for refuse incineration equipment), the concentration figures are divided into 20 classes of equal range. A scheme for the production and evaluation of measured values is shown in Figure 8. These values are not classified in the true sense, but are counted in the computer memory. The emission limit value corresponds to the upper limit of Class 10. Values that exceed twice the limit value are counted in Classes 21 and 22.

Figure 8. Collection and processing of measured values

The legally prescribed evaluation calculations should be carefully noted. For example, according to TA Luft and 13th BImSchV, emission values are considered to have been complied with if

1. Overall daily mean values do not exceed the emission limit value
2. 97 % of all half-hour mean values do not exceed six-fifths of the emission limit value
3. Overall half-hour mean values do not exceed twice the emission limit value

For refuse incineration plants a different kind of evaluation is required [424], [433].

The limits of these two classes correspond to the tolerance range established in the calibration. In Class 23 is stored the number of half-hour mean values that exceed 1.2 times the limit value, up to the limit of the confidence range. The special classes are used to store the half-hour mean values which did not represent true measurement values for more than one-third of the measurement time because of breakdowns or maintenance work on the analyzers (Class 24). The classification of half-hour mean values is shown schematically in Figure 9.

Figure 9. Classification scheme for half-hour mean values

The total number of these values, including those values that were integrated over less than two-thirds of the normal measurement interval owing to plant startup or shut-down are also counted in Class 26. In the absence of the reference value of oxygen due to a breakdown of the measurement equipment, the evaluation computer uses a substituted figure for O_2 which is established in the calibration. All half-hour mean values that were obtained using a substituted figure are classified in the normal way and also counted in Class 25. As well as counting the daily mean values in three classes (30, 31, and 32), the operating times of the plant during the day and the year are stored and reported (Classes 33 and 34). Class 35 is used to store all measured values where twice the limit value has been exceeded.

The time and date of each event is also recorded. Transmission of the data, i.e., the numbers of measurements counted in the 20 normal classes and special classes and the stored data takes place daily automatically at a fixed time. Furthermore, all the data is also transmitted at the end of each calendar year. The daily print-outs give continuous documentation of the emissions from the plant. The annual print-out provides information for the supervisory authority.

Evaluation computers tested for suitability include those manufactured by Durag, Gesytec, Industrie Electronic Schmitz, Maihak, NIS Ingenieurgesellschaft, Nukem, Sick, and RWE.

6.6. Measurement of Gas Velocity and Flow Rate

Normally, only the mass concentrations of the pollutants are measured for the control of emissions. However, in some cases, the emission mass flow rate of a pollutant must be measured discontinuously or continuously. It is determined as the product of the mass concentration and the exhaust gas volume flow rate. The mass flow rate can usually be calculated with sufficient accuracy from known plant parameters such as fuel consumption or steam production rate. If the operating parameters of the plant fluctuate widely or if the quality of the fuel is not known accurately, a direct determination of the volume flow rate of the exhaust gas must be carried out. Thus, for example, the regulation covering waste incineration plants usually requires continuously recording volume flow rate measurement [424]. The minimum requirements should be referred to (see Section Minimum Legal Requirements).

Discontinuous Methods. To calculate the volume flow rate $\dot{V}$, the mean velocity $\bar{v}$ in the measured cross section must be determined. The requirements that apply to the properties of the measured ducting (undisturbed inlet and exit) are described in the VDI Guideline 2066 [428]. The mean flow rate is determined by point velocity v_i measurements carried out in a grid arrangement covering the entire measured cross section. For emission measurements, the arithmetic mean is obtained in accordance with the instructions given in VDI 2066, which also specifies the number of measurement points (see Section Measurement of Particles).

The value of $\bar{v}$ is given by

$$\bar{v} = \frac{1}{n}\sum_i vi$$

The mean volume flow rate $\dot{V}$ is given by $\dot{V} = \bar{v} \cdot A$, where A is the measured cross section.

Pitot tubes are used for manual measurement. The dynamic pressure is measured as the difference between the total pressures p_{tot} and the static pressure, and the local velocity is then given by

$$v = \sqrt{\frac{2}{\varrho}(p_{tot} - p_{stat})}$$

The Prandtl modification of the Pitot tube is widely used (VDI 2066). In the case of different Pitot tube designs, correction figures determined in fluid-dynamic experiments in a wind tunnel are sometimes used. The measurement range of the Prandtl tube is ca. 2 – 50 m/s. Anemometers are used for lower velocities; when used in stack gases special calibration conditions and the influence of gas temperature and gas properties on the reading must be considered.

Continuous Methods. Methods for the continuous measurement of gas velocity and volume flow rate include dynamic pressure difference methods with transducers, ultrasound measurements by the time-difference method, and determination of turbulence frequency by ultrasound measurement.

Dynamic pressure measurements usually require several openings on the upstream side which enable the mean total pressure over the cross-sectional area of the exhaust gas duct to be measured. Using the arrangement of measurement points specified in VDI 2066, with equal grid unit areas, the probe must be fitted at each of these points. For velocity measurement based on the determination of the turbulence frequency by its modulating effect on an ultrasound beam, precalibration must be carried out by the manufacturer for each user. In time difference measurement by ultrasound, the signals pass through the gas stream at an angle α in two directions. Each of the two transducers acts as both a transmitter and a receiver.

Equipment that operates according to these principles has now been officially approved. Note that all methods and equipment in the grid measurement system must be calibrated by carrying out simultaneous velocity measurements with a reference method, usually dynamic pressure measurement by the Prandtl method. Calibration is discussed in Section Testing and Calibration of Measurement Equipment.

6.7. Measurement of Particles

Both manual and continuously recording methods can be used for measuring particulate materials. The manual methods and some of the recording methods are described in VDI 2066. When using recording methods, the minimum legal requirements (see Section Requirements for Continuous Measurement and Associated Computer Systems) and the certification of suitability must be complied with. The manual methods are proven, but problems can occur with very low dust contents (<1 mg/m^3) and moist, supersaturated exhaust gas (e.g., after it has passed through water scrubbers). Although methods of continuous measurement are available, not all are equally suitable. For example, it is not possible to work with optical transmission equipment on supersaturated exhaust gases. Also, it is unsuitable for gases with low dust content inducts providing small optical path lengths. With exhaust gas saturated with water vapor, extractive sampling and reheating techniques are used.

The measurement principles used include the measurement of extinction, light scattering, and radiometry. For low dust contents, the more sensitive method based on scattered light measurement is used.

6.7.1. *Sampling*

The sampling of particles in a flowing exhaust gas must take place at the same velocity as that of the gas to prevent segregation or disturbance of the particle-size distribution due to the inertia of the particles, leading to falsification of the measured solids content. If the sampling rate is too high, the measured dust content will be too low, and vice versa. This mechanism depends on the particle size distribution. For particles of aerodynamic diameter <0.5 µm, the effect of this inertia is practically negligible. A schematic diagram of equal velocity sampling is given in Figure 10.

Figure 10. Scheme for equal velocity sampling

a) Sampled gas stream $\dot{V}$; b) Main gas stream $\dot{V}$; c) Sample probe

A = cross-sectional area; $A_{\dot{V}}$ = cross-sectional area of sampled gas stream = effective cross-sectional area of probe; v = velocity

Equal velocity condition: $v_{\dot{V}} = v\dot{V}$; Equal flow rate condition: $A_{\dot{V}} \cdot v\dot{V} = A_S \cdot v_S$

Another important aspect of sampling is that only part of the flowing gas in the measurement grid is removed. As the gas velocity and the dust flow can only be measured at certain points in the measurement cross section, the measurement points chosen must be representative. The gas and dust flow rates must be determined as accurately as possible using a suitable number and position of measurement points within acceptable time scales and at acceptable labor cost.

For this measurement process, the total area is subdivided into smaller regions of equal area whose mid-points are used as the measurement points (grid measurement). It is assumed that at each point the gas velocity and the mass flow rate represent the mean for the small area. For rectangular cross sections, the areas should be similar. The arrangement of measurement points in a rectangular cross section is shown in Figure 11. With a circular cross section, the measurement plane is divided into annular regions of equal area. The typical measurement points for circular cross sections are illustrated in Figure 12. Measurements are generally carried out on two perpendicular axes (diameters). For very uniform flow, a single measurement axis may suffice, although in exceptional cases more than two axes may be required.

Figure 11. Arrangement of measurement points in a grid-based measurement in a rectangular cross section

Figure 12. Arrangement of measurement points in a grid-based measurement in a circular section with two measurement axes

$$a_n = D^1/_2\left(1 \pm \frac{2i-2h+1}{2i}\right) = DK_n$$

where i = number of surface elements, n = ordinal number

The necessary number of equal rectangles or annular areas depends on the flow distribution and the area of the measured cross section. Increased nonuniformity of gas and dust distribution means that more measurement points must be provided.

For a cross-sectional of 0.03 – 1 m^2, four measurement points are required, and for >1 m^2, four per square meter.

However, as a rule, 20 measurement points are sufficient for larger cross-sectional areas.

6.7.2. *Discontinuous Methods*

Particles can be measured discontinuously by various gravimetric methods, by optical methods in which the DIN smoke number is estimated visually, and by visual estimation of the gray value (Ringelmann method).

Gravimetric Determination. A probe removes a sample stream of dust-laden gas from the total volume flow, and the particles present in the sampled gas are collected on filters made of glass, quartz fiber, or quartz wadding. The dust content is found from its mass and the volume of sampled gas [428], [452-454]. In this method, particles are recovered under the conditions prevailing in the exhaust gas duct, and the filter is located immediately after the sampling probe.

These methods are used to determine particulate emissions, to investigate the efficiency of particle separators, and as reference methods for calibrating recording dust content measurement equipment.

A sampling arrangement for moist, saturated off-gases is described in VDI 2066, Sheet 3, in which the filter is located outside the duct. The sampling probe and the filter are heated so that the particles are collected at temperatures above the exhaust gas temperature (i.e., “quasi-dry”).

A method for determining the dust content of the unpurified gas (up to 200 g/m^3), i.e., before the dust filters, is described in VDI 2066, Sheet 3. A sampling flow rate of ca. 4 m^3/h is used with a double filter cartridge with higher dust storage capacity.

The measurement method described in Sheet 2 is used in practice for dust contents of 1 – 1000 mg/m^3. For concentrations of <20 mg/m^3, a packed cartridge/flat filter combination is used. The arrangement described in Sheets 2 and 7 is illustrated in Figure 13.

Figure 13. Sampling equipment (VDI 2066, Sheets 2 and 7)

a) Filter head with probe and diffuser; b) Gas sampling pipe; c) Shut-off valve; d) Drying tower (if necessary); e) Protective filter for suction equipment; f) Suction equipment (leak-proof); g) Bypass control valve; h) Flowmeter (rotameter); i) Gas meter with thermometer; j) Barometer; k) Timing instrument; l) Temperature sensor with display; m) Prandtl tube with micromanometer (alternatively anemometer); n) Gas measurement equipment (if necessary)

This arrangement requires leak-proof suction equipment with a by-pass and a flow-control valve. If the suction equipment follows the gas meter, the volume flow rate can be controlled by bleeding in air.

The method of VDI 2066, Sheet 7 is suitable for measuring low dust contents (0.1 – 20 mg/m^3). For the range 0.1 – 5 mg/m^3, weighing must be very accurate. The system is designed for sampling rates up to 4 m^3/h. A typical flat filter head is shown in Figure 14. The same method is used for measuring asbestos dust [455].

Figure 14. A typical flat filter head

a) Exchangeable sampling probe; b) Inlet cone; c) Union nut; d) Seal; e) Tension ring; f) Filter holder; g) Flat filter; h) End housing and connection piece

d_1 = diameter of housing (65 mm); d_2 = diameter of filter (50 mm); l_1 = length of inlet tube (10 mm), l_2 = length of flat filter head (100 mm); α = angle of inlet cone (30°)

The relative detection limits for the various dust measurement methods with the usual operating time of 30 min are 1 – 2 mg/m^3 with the 12 or 4 m^3/h filter head, 0.3 – 0.5 mg/m^3 with the 40 m^3/h filter head, and 0.1 – 0.2 mg/m^3 with the flat filter head.

Lower detection limits can be achieved by increasing the gas sampling rate or using longer running times. With a dust content of ca. 10 mg/m^3, duplicate determinations indicate approximate measurement uncertainties *U* (95 %) of between ± (5 – 10) % with the 4 – 40 m^3/h equipment, and between ± (4 – 8) % with the flat filter head equipment.

Optical Methods. In the past, visual methods were prescribed for monitoring dust and smoke emissions. Official regulations at one time specified the Ringelmann method for checking the acceptability of exhaust gas plumes. However, now that dust contents are much lower, this requirement is now regarded as obsolete.

The Ringelmann scale is a series of gray values between white and black in five steps from 0 % (white) to 100 % (black). Estimation is carried out with a chart having four areas covered with black hatched lines that occlude 20, 40, 60, and 80 % of the area, giving the impression to the eye of different gray values.

For combustion plants running on light heating oil, smoke emission limits must be complied with. Smoke emission is represented by the smoke number (DIN 51 402, Part 1), which is determined with a manual smoke pump. The value is determined from the change in the reflectivity of the measuring filter. An increase in the smoke number of 1 unit is defined as a decrease of 10 % in the reflectivity of the measurement filter.

This method is mainly designed for monitoring small furnaces. For plants fired with light heating oil with a thermal capacity ≥ 5 MW, TA Luft requires continuous monitoring of the smoke number. These recording devices must be calibrated against a conventional measurement method. The DIN method using manual smoke pumps is unsuitable. A modified method is described in VDI 2066, Sheet 8 [456], based on DIN 51 402, Part 1. It is a photometric method developed from a technique for measuring low dust contents [454].

6.7.3. *Continuous Methods*

Where there is a legal requirement for equipment for continuously measuring emissions, the conditions described in Section Requirements for Continuous Measurement and Associated Computer Systems must be observed. Measurements carried out at the instigation of internal plant management are not affected.

6.7.3.1. *Optical Methods*

Optical monitoring of dust emissions is widely used, based on transmission/opacity, extinction, or scattered light.

In in-situ photometric dust measurement, the intensity of a beam of light passed through the off-gas duct is decreased as a result of absorption and scattering by the particles. The ratio of attenuated to emitted light is the optical transmission *T*. The quantity 1 – *T* is known as the opacity. The value log (1/*T*) is the extinction *E*.

The relationship between the length of the light beam *L* and the transmission *T* for constant dust properties in the exhaust gas is expressed by the Lambert – Beer law:

$$T = \exp(-E) = \exp(-\varepsilon L)$$

The extinction coefficient ϵ depends on the properties of the light used, the properties of the dust to be measured (e.g., shape, color, and particle size distribution), and on the dust content *c*. It has been found that, within certain limits, there is a linear relationship between dust content *c* and extinction coefficient ϵ if other parameters are constant. If ϵ' is the proportionality constant:

$$T = \exp(-\varepsilon' cL) \text{ or } E = \varepsilon' cL$$

Depending on the application, the equipment can be designed for smoke density measurement or dust content measurement. In smoke density measurement equipment, only the transmission is measured. The object is to monitor the functioning of filter equipment and to determine the opacity of the exhaust gas, e.g., by determining its visibility threshold or by using the Ringelmann scale. There are several approved types of measuring equipment [431]. Manufacturers include Durag and Sick.

In dust content measurement equipment, the extinction is measured. An individual calibration by means of a separate determination of the dust content enables the measured extinction values to be calibrated, taking into account the effect of particle properties. Particle-size distributions, densities, colors, and refractive indices differ from plant to plant, but are comparatively constant for the same plant.

The usual arrangement for photometric dust content measurement apparatus in situ is illustrated in Figure 15. The measurement head is installed on one side of the exhaust gas duct and the reflector on the other. The light source and photoelectric detector are located close together in the measurement head. The reflector consists of an arrangement of triple mirrors (retroreflectors) which reverse the direction of the light beam. Thus, the light beam passes through the measurement path to the reflector and is returned. The reference light beam passes through a dust-free reference path inside the measurement head. A half-silvered mirror inserted alternately into the measurement and reference light paths causes the two light beams arrive at the photoelectric detector out of phase. The electrical signal produced by the detector is processed so that the final signal is proportional to the extinction.

Figure 15. Schematic diagram of in situ equipment for photometric dust measurement

Several types of measurement equipment have been approved [431]. Manufacturers include Durag, Mannesmann/H.u.B., and Sick.

Scattered light measurement exploits the fact that when a collimated light beam is passed through a dust-laden measured volume, part of the light is scattered in various directions. The intensity of the light scattered at a given angle to the original direction depends on the intensity, wavelength, and polarization of the incident light, on the angle itself, and also on the shape, particle-size distribution, and refractive index of the particles. The principle of scattered light measurement is illustrated in Figure 16. As with extinction measurement, a linear relationship exists between the dust content and scattered light intensity within certain limits. The sensitivity of light scattering measurement equipment is considerably higher than that of extinction measurement equipment. Depending on the method used, the detection limit can be as low as 0.1 mg/m^3. In practical applications, dust concentrations as high as 100 mg/m^3 have been determined. However, with both extractive sampling and in-situ equipment (small measurement volumes), care must be taken to ensure that sampling is representative.

Figure 16. Principle of scattered light measurement

a) Incident light beam on sample; b) Light beam transmitted through sample; c) Sample; d) Scattered light; e) Measurement of selective scattered light beam; f) Photocell

The function scheme of the KTN/KTNR photometer manufactured by Sigrist is illustrated in Figure 17. This operates according to the double beam system, with forward scattering at 15° and automatic compensation.

Figure 17. Functional scheme of a scattered light photometer

a) Light source; b) Flicker mirror; c) Measurement beam; d) Reference beam; e) Light attenuator; f) Display instrument; g) Reference standard; h) Measurement chamber; i) Light detector; j) Measurement amplifier

1) Measurement position of flicker mirror; 2) Reference position of flicker mirror

The beam from a light source (a) passes through an optical path to the “flicker” mirror (b). In position (1), this deflects the incident light as the measuring beam (c) via an optical path into the measuring chamber (h). Part of the scattered light produced by the sample is received at an angle of 15° to the forward direction by a light detector (i) and measured. In position (2), the incident light is passed as a reference beam (d) through a light attenuator (e) and a reference standard (g) to the light detector. The signal currents produced by the light detector are compared in a measurement amplifier (j) and converted into a control signal which changes the reference beam by means of a light attenuator until its intensity corresponds to the intensity of the light which is scattered by the sample and falls on the light detector.

The measurement method and calibration are described in VDI 2066, Sheet 6 [457]. The equipment operates with an extractive sampling system. The sampling system can be heated to 180 °C, so that even water vapor saturated exhaust gases can be continuously measured [431], [434]. In another approved variation, the equipment is used to measure the smoke number [458].

In-situ scattered light photometers are produced by Durag and Sick for measuring both low dust contents and smoke numbers.

A schematic diagram of equipment for in-situ scattered light measurement is shown in Figure 18 [456]. This is suitable for measuring both dust contents and smoke numbers. Light is passed directly through the exhaust gas duct and received and absorbed on the opposite side by a light trap. The scattered light from a definite measured volume in the exhaust gas duct is received and measured at a certain angle (e.g., 90° scattering or back-scattering). Because of the geometry of the equipment, the measured volume lies near to the duct wall. Problems can therefore arise on installing this equipment in thick-walled ducts (e.g., brick-lined) or double-walled pipe. In-situ light scattering equipment is sensitive and suitable for measuring low dust contents (<10 mg/m^3) and low smoke numbers (< 3 or < 1). Unlike extinction equipment, it can be operated in narrow ducts. Various types of equipment have been approved [434], [435], [449], [458].

6.7.3.2. *Radiometric Methods*

Radiometric measurement equipment is manufactured by the companies Verewa (dust content, smoke number) and FAG Kugelfischer (dust content), and has been officially approved [451]. (Smoke number measurement equipment is based on reflection photometry rather than β-radiation.) In dust measurement based on β-radiation absorption, a sample gas stream is taken by a probe and passed through a strip of filter paper which collects the dust particles. The paper strip is moved along in a stepwise fashion. The quantity of dust deposited on the filter is measured by the attenuation of β-radiation (source: ^{14}C or ^{85}Kr) passed through the filter. The attenuated radiation is detected by a Geiger counter, and the attenuation is a measure of the mass of dust collected (Fig. 19).

Figure 19. Principle of radiometric measurement of dust by β-radiation absorption

a) Filter band; b) β-Emitter; c) Partial stream; d) Detector; e) Amplifier; f) Display

As with the other methods, calibration is based on a conventional measurement method, carried out as a grid measurement over the duct cross section.

In the Beta-Staubmeter F 904 equipment (Verewa), a sample stream is taken isokinetically from the gas flowing in the duct, and preheated dilution air is added to reduce the dew point of saturated exhaust gases. The gas is then filtered and the dust collected is measured using β-radiation. The result is the mean value of the dust content based on the cycle time used. The dust measuring equipment FH 62 E – NA (FAG) measures the actual dust content radiometrically. After the zero has been automatically set, a sample stream of gas is removed from the stack isokinetically. It is then heated, diluted with clean air, and aspirated through a measuring filter. The continuously increasing amount of dust on the filter causes the integral signal obtained to increase with time. An instantaneous dust concentration is obtained from the signals for rate of mass increase and flow rate.

In another continuous measurement method, the gas is extracted by a sampling probe which simultaneously measures the gas velocity. The dust-laden gas is trapped on a filter, which is changed at a time interval depending on the amount of dust collected. The dust is determined by measuring the differential pressure across the filter (LSP apparatus, Becker Verfahrenstechnik).

6.7.4. ***Particle Size of Dusts***

Laboratory methods for determining the particle size of dusts include microscopy, sieving, air classification, sedimentation, and scattered light [459]. Dust quantities of 2 – 20 g are necessary. With low dust contents, relatively large volumes of the exhaust gas must be filtered. However, the particle size distribution can be changed by the sampling and collection processes (e.g., by agglomeration). Redispersion in the laboratory may result in the measured particle size differing from that in the gas [460]. It is therefore advantageous to measure the particle-size distribution in the gas. Various types of measurement equipment have been developed, e.g., light scattering, diffuser batteries, electrostatic aerosol analyzers, and aerosol centrifuges. Sampling must be carried out with a suction probe, as the equipment cannot be directly installed in the exhaust gas duct. A high proportion of particles of diameter > 3 µm are lost during collection by deposition on the walls of the probe and on the inlet to the measuring equipment. The method is therefore limited to particles of diameter < 3 µm, although particles in the range <1 to 100 µm can be expected in emissions from industrial and commercial plants. Aerosol measurement equipment generally cannot be used in hot and chemically aggressive exhaust gases. The sampled gas stream should not be strongly cooled because condensation of moisture and other substances can change the particle-size distribution. Cascade impactors are suitable for sampling a partial gas stream and separating the particles into mass fractions. They can be used directly in hot, chemically aggressive gases [461]. Gravimetric evaluation of cascade impactor measurements gives mass distributions as a function of aerodynamic diameter of the particles. However, this method does not replace the measurement of total dust content (VDI 2066, Sheets 2, 3, and 7). The cascade impactor method is described in detail in VDI 2066, Sheet 5 [462]. Cascade impactors can separate particles into several fractions between ca. 0.3 µm and 15 µm, depending on the design, the type of gas, and the particle properties. Larger particles (> 10 µm) interfere with the fractionation process and must be removed by a preliminary separation process [463]. Low-pressure impactors are used for particles with a lower size range.

The impactor exploits differences in the inertia of particles to separate them into fractions. An impactor stage consists of a jet and an impact plate. The particles are accelerated in the jet and those having sufficient inertia strike the impact plate and are collected (see Fig. 20).

Figure 20. Principle of impaction of particles

The particle fractionation depends on jet width *D*, jet length *L*, and the distance *S* between the impact plate and the jet. Cascade impactors consist of several impactors in series, whereby particles of decreasing inertia are separated in the successive stages, giving fractions of decreasing particle size. Particles not collected on the impact plates are trapped on a filter.

Evaluation of impactor measurements is based on experimentally determined median values of the Stokes number St_{50} and the limiting aerodynamic particle diameter d_{ae50} of an impact stage. For an impactor with several circular jets per stage, a uniform value of St_{50} = 0.26 is used for all impactor stages for reasons of comparability [461].

The measurement setup is specified by VDI 2066, Sheet 7. The gas passes through the sampling probe, the cascade impactor, and then the angle bend. Without a preliminary separation stage, the cascade impactor described in VDI 2066, Sheet 5 can be used for dust contents of 1 – 2 mg/m^3. The impactor must not be overloaded. The maximum permissible load per stage is ca. 100 mg. If there is a preliminary separation stage, the dust content can be between 5 mg/m^3 and 25 g/m^3, depending on the fraction of coarse particles.

6.7.5. *Heavy Metals as Dust Constituents*

It is a legal requirement that all emissions of metals, metalloids, and their compounds should be measured [422-424]. Their emission limit values lie in the range 0.05 – 5 mg/m^3. These limits are defined as the sum of the concentrations of the substances in the form of dust, gas, and vapor. The duration of an individual measurement should normally be 30 min and should not exceed 2 h. The most important elements are antimony, arsenic, beryllium, lead, cadmium, chromium, cobalt, copper, manganese, nickel, palladium, platinum, mercury, rhodium, selenium, tellurium, thallium, vanadium, zinc, and tin. A proven measurement method is described in VDI 3868, Sheets 1 and 2 [464], [465]. It consists of a particle collection system (VDI 2066) and an absorption stage made up of a battery of wash bottles, as used for measuring emissions of gases such as SO_2 and HCl (Fig. 21). The exhaust gas is sampled isokinetically by a probe. The particles are retained by a filter system as specified in VDI 2066, Sheet 2 or Sheet 7. The materials passing through the filter are drawn through a heated sampling tube. A bypass stream is passed through one or more absorption systems in parallel, consisting of at least three gas-absorption bottles in series. The method enables the mass of the dust and of its constituents to be determined both per unit of time and per unit of volume. Two types of absorption solution are used:

1. Solution A: 3 volumes hydrochloric acid mixed with 1 volume nitric acid, 1 volume of this mixture being diluted with 9 volumes water
2. Solution B: 1 volume nitric acid mixed with 1 volume hydrogen peroxide, 2 volumes of this mixture being diluted with 13 volumes water

T = temperature measurement; P = pressure measurement; G = gas analysis; v = gas velocity measurement

Mercury is determined with a solution of 20 g $KMnO_4$ in 1 L dilute sulfuric acid (VDI 3868, Sheet 2).

Under the usual sampling conditions, the detection limit for metals is usually <0.01 mg/m^3. The method described in Guideline VDI 3868, Sheet 2 for mercury is suitable for concentrations of >5 µg/m^3 [465]. Both methods are especially suitable for measurements on exhaust gases from thermal processes in which the constituent elements can accumulate on the smallest particles as well as being present in gaseous and vapor form.

The most important methods of analysis include X-ray fluorescence (XRF), atomic emission spectrometry with inductively coupled plasma source (ICP – AES), atomic absorption spectrometry (F-AAS and G-AAS), and instrumented neutron activation analysis (INAA). Analytical determination of the elements is described in VDI 2268 [466-469]. Because of the required detection sensitivity, atomic absorption is used preferentially for many components. Methods used include flame AAS, graphite-tube AAS, the hydride and cold vapor technique, and ICP – AES. In cases where even atomic absorption spectrometry does not enable all trace elements to be determined with sufficient sensitivity, INAA can be used if available.

6.8. Measurement of Gaseous Inorganic Emissions

6.8.1. *Sampling*

A measurement grid is necessary when sampling gaseous emissions if the concentration is not uniformly distributed over the measured cross section [439]. There are two methods of determining the mean concentration. Either the local

emission concentration c_i and the local velocity u_i (together with the oxygen content) are determined at each measuring point, or a partial mass m_i is determined by using a collection phase, with a sampling rate proportional to the velocity. However, this does not necessarily mean isokinetic sampling (as with dust measurement), but a sampling rate proportional to the velocity or the mass.

Generally, gaseous emissions are sampled at a velocity considerably lower than that of the exhaust gas. Also, the probe is not parallel to the flow direction as with dust measurement, but at an angle <90° to the flow direction. The sampling volume rate is typically 30 – 120 L/h. The probe is made of, e.g., glass, quartz, titanium, stainless steel, or PTFE. The probes and associated pipework are usually heated to prevent condensation.

With recording analytical equipment that operates extractively, correct functioning and the results obtained depend on the processing of the sampled gas, which must be dust-free, dry, and free of corrosive materials before it enters the analyzer. Furthermore, the volume flow rate, pressure, and temperature must generally lie within limits imposed by the measurement method. If the dew point of the sampled gas is higher than the temperature of those parts of the analysis system with which it comes into contact, the gas must be cooled at the exit of the sampling equipment before it enters the analyzer to condense the moisture. The possibility as the substances being measured dissolving in the condensate must be considered.

6.8.2. *Sulfur Oxides*

When sulfur-containing fuels and wastes are burnt, sulfur dioxide is formed. Important emission sources are industrial furnaces, chemical plant, the cement industry, metal smelting, ceramics, the cotton industry, domestic heating, and traffic. Part of the SO_2 may be oxidized to SO_3. It is normally a legal requirement that the total sulfur oxides (SO_2 + SO_3) should be determined and expressed as SO_2.

6.8.2.1. *Discontinuous Methods*

At present, four manual analytical methods are available for determining SO_2, and these are also used as reference methods for the calibration of continuously measuring equipment. They are described in the Guideline VDI 2462, Sheets 1, 2, 3, and 8 [470-473] (Table 12).

Table 12. Determination of SO_2 (VDI 2462)

Sheet	Brief title	Measurement principle	Remarks
1	Iodine – thiosulfate method	bubbling into I_2, oxidation to H_2SO_4, back-titration with sodium thiosulfate, detection limit 60 mg SO_2/m^3	cross-sensitivity towards hydrogen sulfide, nitrogen oxides, halogens; suitable for higher SO_2 concentrations
2	Hydrogen peroxide oxidation + titration	oxidation to H_2SO_4 by H_2O_2, titration with NaOH, detection limit 30 mg SO_2/m^3	cross-sensitivity towards components that can form acids or bases in the absorption solution; suitable for higher SO_2 concentrations
3	Hydrogen peroxide oxidation + gravimetric determination	oxidation to H_2SO_4 and precipitation of $BaSO_4$, detection limit 40 mg SO_2/m^3	cross-sensitivity towards other sulfur-containing components except SO_3; suitable for higher SO_2 concentrations
8	H_2O_2 – thorine method	oxidation to H_2SO_4, titration with $Ba(ClO_4)_2$ with thorine as indicator, detection limit 0.72 mg SO_2/m^3	cross-sensitivity towards certain anions and metallic cations and other sulfur-containing components except SO_3; suitable for low SO_2 concentrations; no cross-sensitivity towards nitrogen oxides

Because of the low limits of detection and lack of cross-sensitivity towards nitrogen oxides, the method described in Sheet 8 is often used for emission measurements and as a reference method for the calibration of continuous measuring equipment. The gas is sampled through a heated probe, and is then passed through a heated silica wool filter to remove dust and through two wash bottles in series containing a 3 % solution of hydrogen peroxide. The temperature of the heated probe and the silica wool filter is chosen so that condensate formation (acid dew point) is prevented. A temperature of 200 – 220 °C is adequate. The SO_2 in the exhaust gas is quantitatively oxidized to H_2SO_4. This method also determines SO_3 and is thus a summation method for sulfur oxides (SO_2 + SO_3) expressed as SO_2. A schematic diagram of the sampling apparatus is given in Figure 22. Analysis is by titration against a solution of barium perchlorate. A color change takes place in the presence of the added metal indicator thorine when the solubility product of barium sulfate is exceeded.

Figure 22. Schematic of sampling equipment for the measurement of sulfur oxides

The separate determination of SO_3, described in Sheet 7 [474], is also based on the thorine reaction. The SO_3 is absorbed in isopropanol, which does not absorb SO_2. The SO_3 in isopropanol solution is titrated with barium perchlorate with thorine as indicator, as described for SO_2. The relative detection limit is ca. 2 mg/m^3. Volatile sulfates that pass through the filter are also determined.

6.8.2.2. *Continuous Methods*

Several photometric measurement principles can be used for continuously measuring SO_2 emissions, with extractive and in-situ sampling. Conductivity methods are also used, with extractive sampling.

Photometry with Extractive Sampling. All heteroatomic molecules such as CO, SO_2, and NO have a characteristic absorption spectrum in the infrared; SO_2 and NO also absorb in the ultraviolet.

The simplest arrangement for an extractive absorption photometer is illustrated in Figure 23. The light from a radiation source passes through an optical filter to limit its spectral range to that required for the measured component, passes through an optical cell through which the gas being analyzed flows, and falls on a photodetector linked to an electronic signal processing device. Part of the light is absorbed by the pollutant molecules. The light attentuation is therefore a measure of the concentration of the pollutant. In this simple arrangement, very small changes in the radiation emission and the receiver sensitivity lead to unacceptably high zero point errors. Measures to avoid this problem are based either on a periodic zero point correction or a reference standard in the form of a second reference filter or a reference gas. This reference standard can either be inserted from time to time (and thus out of phase) into the radiation path, or it can be located in a parallel reference beam. The first arrangement is known as a single-beam photometer, and the second a double-beam photometer. The photometric analysis equipment can be caused to be sensitive to a selected component using either dispersive or nondispersive systems.

Figure 23. Absorption photometer (schematic)

Dispersive Systems. In dispersive systems, the light from a broad band radiation source is broken down into its spectral components by a spectrometer before the measurement is carried out. Prisms, gratings, or interference filters can be used to perform the dispersion.

Nondispersive Methods. In nondispersive methods, wavelength selection is carried out by the substances being measured, which are stored in the equipment. There are three methods of storage:

1. In the nondispersive infrared (NDIR) method, a gas-filled optical cell is used for storage (Fig. 24). The radiation is deflected to pass through the gas-filled chambers, and modulation by a rotating wheel produces periodic pressure fluctuations in the detector chambers. These are detected either by a membrane capacitor or a microflow detector which detects a flow between the two chambers caused by the pressure fluctuations, and converts this into an electrical signal.
2. In the gas filter correlation (GFC) method (Fig. 25), a gas-filled optical cell attached to a rotating wheel acts as the storage device. This is periodically brought into the radiation path, alternating with a nitrogen-filled gas filter.
3. In the nondispersive ultraviolet (NDUV) method, the component to be measured is stored in the radiation source. Gas-filled discharge lamps are used which emit spectral lines characteristic of the component being measured. UV photometers operate with 1 or 2 beams and with 1 or 2 photoelectric detectors. Some photometers use a combination of two of the optical selection methods described above.

Figure 24. NDIR photometer (schematic)

Figure 25. Gas filter correlation method (schematic)

In-Situ Photometry. The absorption measurement path in in-situ photometers is located directly in the exhaust gas duct, so that the gas sample need not be transported to the optical cell by a sampling system. The photometer, consisting of a photometric detector, wavelength selection equipment, and electronics to calculate the result is situated outside the exhaust gas duct. In the UV range, wavelength selection is by diffraction grating. In the IR range, interference filters and gas-filled filter chambers (as with the GFC method) are also used.

Two arrangements are illustrated in Figure 26. In both cases, the windows on each side of the absorption path are protected from dust soiling by an air curtain, as in the photometric measurement of dust.

Figure 26. In-situ photometer (schematic)

Conductometry. In conductometric gas analysis, the gas sample is passed into a liquid reagent, and the change in conductivity after reaction of the liquid with the gas is measured.

In continuous conductometry, the sampled gas and the reagent liquid are continuously fed into one end of a reaction tube. As the change in conductivity also depends on the ratio of the volume flow rates, both flow rates must be kept constant by a control device. The conductivity before addition of the gas phase and after its removal is measured by two pairs of electrodes (Fig. 27). The conductivity difference, which is proportional to the concentration of the measured component, is calculated by an electronic system. As conductivity is strongly temperature dependent, the effect of temperature must be compensated.

Figure 27. Conductometric measurement (schematic)

Details of officially approved equipment for measuring SO_2 have been published [475] (Table 13).

6.8.3. *Nitrogen Oxides*

Nitrogen oxides are formed in all thermal combustion processes in air and by oxidation of the combined nitrogen in fuel. Emission sources include furnaces burning solid, liquid, and gaseous fuels; internal combustion engines; power plants; cement works, metallurgical plant; waste incinerators; and chemical plant. In general, the concentration of NO_2 is < 10 %, but in a few cases (e.g., fertilizer production), it can be considerably higher.

Discontinuous Methods. Four manual analytical methods are described in VDI 2456. The phenoldisulfonic acid method and the titration method described in Sheets 1 and 2, respectively, are suitable for high concentrations in the g/m^3 range. The sodium salicylate method and the dimethylphenol method described in Sheets 8 and 9 are often used as reference methods for calibrating continuously measuring equipment on account of their low detection limits [476-479].

In the sodium salicylate method, total NO + NO_2 is determined. Sampling can be performed by a gas collection tube or an evacuated absorption vessel. When the gas collection tube is used, a volume equal to about ten times the volume of the tube is drawn through the sampling apparatus.

If an evacuated vessel is used, it is connected via a three-way tap between the solid filter and the pump. Its volume must be corrected for temperature and pressure. Oxidation to nitric acid is then carried out for 24 h. The nitric acid is reacted with sodium salicylate in a solution of H_2O_2 acidified with sulfuric acid to form nitrosalicylic acid. The anion is then measured photometrically. The relative detection limit, using 1 L gas collection tubes, is ca. 2 mg/m^3 (as NO_2). The total time between sampling and obtaining the result is 2 d.

In the dimethylphenol method, ozone is used as oxidizing agent. NO and NO_2 are oxidized by ozone in the gas phase to form dinitrogen pentoxide. The reaction takes place in 5 – 10 min. The N_2O_5 is absorbed in water, forming nitric acid. Samples are taken through a critical jet into an evacuated gas sample container. A schematic of the sampling and oxidation equipment is given in Figures 28 and 29.

Figure 28. Sampling equipment for measurement of nitrogen oxide emissions (schematic)

Figure 29. Example of oxidation equipment

a) Oxygen cylinder; b) Pressure reducer; c) Ozone generator; d) Water cooling (if necessary); e) Gas sample container with isolation valve; f) Wash bottles, the last of which containing; water g) Waste gas

The evacuated gas sample container is filled in the bypass to ca. 500 mbar with the sampled material, and, after temperature adjustment (ca. 5 min), is then filled with ozone until the pressures are equalized. Oxidation is complete after ca. 5 min. The nitric acid formed is reacted with 2,6-dimethylphenol (DMP) in a solution containing sulfuric and phosphoric acids to form 4-nitro-2,6-dimethylphenol. The 4-nitro-2,6-dimethylphenolate anion formed in alkaline solution is measured photometrically at ca. 430 nm. The relative detection limit is 15 mg/m^3, expressed as NO_2.

Ammonia at levels up to 150 ppm does not cause problems. If high concentrations of SO_2 are present in the exhaust gas, there is a risk of formation of other nitrogen-containing products (e.g., N_2O). It is then preferable, after pressure measurement, first to fill the evacuated gas sample container with ozone to ca. 250 – 300 mbar, then to add the gas being measured to ca. 700 mbar, and then to fill with ozone until the pressure is equalized.

As the time required to obtain an analytical result is short, this method is widely used for calibrating continuously measuring equipment in situ.

Continuous Methods. There are several methods of continuous measurement which use both extractive and in-situ sampling techniques. The measurement principles used are infrared and ultraviolet absorption, chemiluminescence reaction, and amperometric measurements with electrochemical cells. As a rule, only the component NO is selectively measured. However, equipment for selectively measuring NO_2 is also commercially available. By combining two analyzers in a single item of equipment, NO and NO_2 can be measured simultaneously. Various types of equipment measure NO and NO_2 sequentially. In the chemiluminescence method, a converter can be incorporated for reducing NO_2, so that total NO + NO_2 is measured [480]. Legal requirements are concerned with the determination of total nitrogen oxides (NO + NO_2) only. The manual method described above can be used to determine the concentration of NO_2 for calibration purposes if NO-selective equipment is used for continuous monitoring, provided that the proportion of NO_2 does not exceed 5 – 10 %. Measurement by IR and UV absorption is described in Section Sulfur Oxides.

The chemiluminescence method is based on the reaction of nitrogen monoxide with ozone:

$$NO + O_3 \rightarrow NO_2 + O_2$$

Some of the nitrogen dioxide molecules formed (ca. 10 %) are in an excited state (NO^*_2) The excitation energy is partially released in the form of chemiluminescence

$$NO_2^* \rightarrow NO_2 + h\nu$$

At constant pressure, constant volume flow rate, and with a sufficient excess of ozone, measurement of the intensity of the radiation in the wavelength range 600 – 660 nm enables the concentration of nitrogen monoxide to be selectively measured. Commercial equipment operates at a pressure equal to or less than atmospheric pressure in the measurement chamber [481], [482]. Equipment legally approved for NO/NO_2 measurement is listed in Table 14.

Sick	GM 30	single-beam photometer with reflector, measurement of the absorption spectrum in certain wavelength regions of the UV

Selective measurement of NO_2 can be carried out by the Perkin – Elmer multicomponent system MCS 100 CD, the Opsis multicomponent system AR 602 Z, the Rosemount NO_2-UV Binos, and the combined equipment Binos 1004 (selective for both NO and NO_2). In the chemiluminescence equipment, it is possible to determine NO_2 from the difference sum (NO + NO_2).

6.8.4. *Carbon Monoxide*

Carbon monoxide can be produced by the incomplete combustion of solid, liquid, and gaseous fuels and waste and is therefore likely to occur in the exhaust gases of all combustion plants. Other sources include internal combustion engines and gas turbines. Depending on the raw materials and the technological processes used, carbon monoxide emissions are produced by installations in the cement industry, the metal smelting industry, iron and nonferrous metal treatment plants, and ceramics.

Discontinuous Methods. The iodine pentoxide method described in the VDI 2459, Sheet 7 for the manual determination of carbon monoxide concentration is a reference method [483]. The principle is the oxidation of CO in the sampled gas to CO_2 with liberation of an equivalent quantity of iodine. The sample is passed over iodine pentoxide (I_2O_5) in a furnace at high temperature.

The iodine is absorbed in a solution of sodium hydroxide and oxidized with bromine to iodate. The iodate is reacted with potassium iodide to form iodine, which is titrated against a solution of sodium thiosulfate. Interfering substances are removed by various adsorption methods during sampling.

Either the exhaust gas is passed via the sample probe directly into the CO combustion furnace, or, more commonly, sampling is carried out with a gas collecting container (gas mouse), and the analysis is then carried out in the laboratory. The schematic design is shown in Figure 30. The working range of the method is between 10 mg/m^3 and 1.25 kg/m^3 CO. The relative detection limit is 2.5 mg/m^3 CO with a sample volume of 4 dm^3.

Continuous Methods. The continuous measurement of CO by NDIR absorption is described in Sheets 1 – 5 of VDI 2459, and the measurement principle in Sheet 6. These sheets are now partially obsolete, having been superseded by BMU (Bundesministerium für Umwelt) approval of certain measurement equipment, including that for the determination of CO concentration by the IR absorption method. Two manufacturers use the gas filter correlation system; one type of equipment includes an electrochemical cell (Table 15).

6.8.5. *Fluorine Compounds*

Gaseous fluorine compounds can occur in the exhaust gases of combustion plants burning solid, liquid, and gaseous fuels and waste, chemical plants, metal treatment plants, and plants for processing rocks and earth.

Discontinuous Methods. Fluorine and gaseous inorganic fluorine compounds can be determined by absorption in sodium hydroxide solution followed by measurement with fluoride-sensitive electrodes or by photometry (method of VDI 2470, Sheet 1) [484]. The exhaust gas is sampled by a heated quartz probe, and is then filtered through a heated quartz wool filter and, if necessary, a heated fine filter or membrane filter to remove dust. It is then passed through two or three bottles filled with sodium hydroxide solution. After steam distillation, the fluoride content of the solution is determined photometrically by the Alizarin Complexone method or potentiometrically with a fluoride-ion-sensitive electrode. With the photometric method, cross-sensitivity effects rarely occur, as the very specific detection reaction is carried out after removal of interfering substances. Measurement with electrode chains gives high selectivity, provided fluoride complex formers such as Fe^{3+} or Al^{3+} are not present in the solution in large amounts. The detection limit is 0.05 mg F^{-}/m^3.

Continuous Methods. Two types of equipment have been officially approved for continuous potentiometric measurement. The gas is passed through a buffered electrolyte solution, and the ion concentration, changes by the substances being measured, is determined by an ion-sensitive electrode system.

In the Bran & Luebbe HF analyzer Sensimeter G, the gas is continuously extracted, passed the probe, the sampling line, the fine filter, and the absorption vessel where it is bubbled through a volume of buffer solution which is renewed every six minutes. The buffer solution is then transported to the ion-sensitive measurement cell. Measurement is thus only semicontinuous. To obtain an accurate result, the reagent solution must be carefully conditioned and its volume accurately measured, and the flow rate of the sampled gas must be constant during the concentration phase.

The Compur Ionotox HF equipment of Compur/Bayer for measuring HF emissions continuously measures the concentration of hydrogen fluoride and other inorganic, gaseous, hydrolyzable fluorine compounds. It is equipped with an electrochemical measurement cell containing an ion-sensitive electrode (fluoride electrode) and a reference electrode (silver/silver chloride). The gas being analyzed is passed continuously through an atomizer where it is mixed with the absorption solution. The latter is fed continuously into the gap between the electrodes whereby the electrode potential is measured. The interfering substances HCl, SO_2, H_2O, CO_2, CO, and NO lead to cross-sensitivity, so that the concentration of these substances must be limited.

6.8.6. *Chlorine Compounds*

Gaseous inorganic chlorine compounds are present in the exhaust gases from combustion plants burning solid fuels and waste materials, and also in the exhaust gases from rock and earth processing plants, the metallurgical industries, and the chemical industry.

Discontinuous Methods. Two methods for measuring chlorine are described in the VDI 3488, Sheets 1 and 2 [485], [486]. The methyl orange method is based on the bleaching effect of elemental chlorine on an acidified solution of methyl orange.

In the bromide – iodide method, bromine is liberated by chlorine from an acidified potassium bromide solution and determined iodometrically. These methods are generally unsuitable for exhaust gases from incineration plants because of

their cross-sensitivity to nitrogen dioxide and sulfur dioxide.

A conventional method for measuring gaseous inorganic chlorine compounds is described in VDI 3480, Sheet 1 [487], with three alternative chloride determination methods: (1) Mohr titration, (2) potentiometric titration, and (3) photometric determination with mercury thiocyanate. The exhaust gas is sampled through a heated silica or borosilicate probe and a heated quartz wool filter, and is then passed into an absorption vessel containing distilled water. Methods (2) and (3) are suitable for HCl contents up to 100 mg/m^3. Methods (1) and (2) are suitable for higher concentrations. The relative detection limits are as follows: method 1: 20 mg/m^3, method 2: 2 mg/m^3, method 3: 2.5 mg/m^3.

Continuous Methods. Several proven types of equipment for the continuous measurement of gaseous inorganic chlorine compounds are commercially available. These make use of potentiometry, conductivity, and NDIR gas filter correlation. The Ecometer and Spectran 677 IR equipment are described in detail in VDI 3480, Sheets 2 and 3, in which the principle, design, and function of the equipment, the construction of the measurement station, and the calibration, evaluation, and parameters of the method are discussed [488], [489]. The Mikrogas conductivity equipment for measuring SO_2 is described in VDI 2462, Sheet 5. A summary of the commercially available equipment is given in Table 16.

Table 16. Equipment for continuous measurement of inorganic chlorine components

Manufacturer	Type	Principle
Bran and Luebbe	Sensimeter G	ion-sensitive electrode, cyclic measurement
	Ecometer	ion-sensitive electrode, absorption path, continuous measurement
Perkin – Elmer	Spectran 677 IR MCS 100 HW	NDIR single-beam photometer, gas filter correlation
Wösthoff	Mikrogas HCl	conductivity, absorption in H_2O_2,
	Mikrogas HCl/SO_2	difference measurement (SO_2 + HCl)–SO_2 with two conductivity cells

The Sensimeter G for HCl operates like the HF equipment of the same name, with a timed collection phase in the measurement cycle. The other equipment described here operates continuously and is based on extractive sampling. In the conductometric method there is cross-sensitivity to HF, which must be calibrated for.

6.8.7. *Hydrogen Sulfide*

Hydrogen sulfide can occur in exhaust gases from coking plants, refineries, synthetic fiber plants, and cupola furnaces.

Discontinuous Methods. Two methods for random sample measurement are described in VDI 3486, Sheets 1 and 2. These are manual analytical methods with potentiometric and iodometric titration [490], [491].

In the potentiometric titration, the test gas is first passed through a solution of hydrogen peroxide and sulfuric acid to remove any sulfur dioxide present, and the hydrogen sulfide is then absorbed in sodium hydroxide solution. The sulfide content of the solution is determined by potentiometric titration with silver nitrate. The relative detection limit is 0.5 mg H_2S/m^3. The method is suitable for determining hydrogen sulfide in exhaust gases. Because hydrogen cyanide and carbon disulfide interfere, the method cannot be used for coke oven gas. When determining hydrogen sulfide in combustion gases, the carbon dioxide content should be taken into account. (The CO_2 is absorbed in the alkaline wash bottle and must be subtracted from the sample volume.)

In the iodometric titration, hydrogen sulfide is reacted with cadmium acetate solution to form cadmium sulfide, which is determined iodometrically after removing the liquid phase and dissolution in hydrochloric acid. The relative detection limit is 1 mg H_2S/m^3. The method is generally applicable and is especially suitable for gases with high concentrations of hydrogen sulfide. Collecting the cadmium sulfide precipitate by filtration and analyzing the filter cake eliminates cross-sensitivity effects.

Continuous Methods. Hydrogen sulfide can be continuously measured and recorded by the Maihak Monocolor equipment. It is based on the colorimetric principle and operates semicontinuously, using a collecting phase and a dry reaction. Selectivity is achieved by means of chemically specific color indicators for hydrogen sulfide (lead acetate, silver nitrate, and silver sulfate), evaluated photometrically. The Monocolor equipment described in VDI 3486, Sheet 3 operates with a reagent paper strip impregnated with color indicators chemically selective for the components to be determined. The paper strip passes stepwise through an optical scanning device [492].

6.8.8. *Ammonia*

Emission sources of ammonia include coking plants and chemical fertilizer plants. In furnaces equipped with reduction catalysts and NH_3 addition (SCR) or with NH_3 addition alone (SNCR) to reduce sulfur emissions, unreacted NH_3 can be measured for monitoring purposes.

Discontinuous Measurement. Two methods are described for ambient air measurements in the µg/m^3 range, namely the

indophenol method and the Nessler method [493], [494]. In both, the sampled gas is passed through dilute sulfuric acid, trapping ammonia as ammonium sulfate. In the indophenol method, the sulfate is reacted with phenol and sodium hypochlorite to form a blue indophenol dye whose concentration is determined photometrically at 630 nm.

In the Nessler method, interfering substances (e.g., SO_2, NO, NO_2, and HCl) are removed by distillation of the ammonia from alkaline solution. If H_2S and formaldehyde are present, they are decomposed by potassium manganate(VII) before distillation. This is followed by reaction with the Nessler's reagent and photometric measurement at 450 nm.

Emission measurements are carried out in accordance with VDI 2461. Sampling is performed with heated quartz tubes leading to quartz or glass absorption vessels. The temperature of the sampling system is adjusted to the exhaust gas temperature, but should not exceed 330 °C. The dust is removed by a heated filter after the probe. The absorption solution is 0.1 N sulfuric acid. A flow rate of ca. 2 m^3/h can be achieved by using two impingers in series. The rate is lower if wash bottles are used. Distillation, reaction with Nessler's reagent, and photometric determination at 450 nm are described in [494]. Determination with a sensitive electrode is also possible. For determinations in accordance with Sheet 2 [494], reproducibility is improved by buffering the reaction solution [495], enabling a detection limit of <0.1 mg/m^3 to be attained.

Continuous Methods. Two types of measuring equipment that fulfil the minimum legal requirements are commercially available. Neither TA Luft, 13th BImSchV, nor 17th BImSchV prescribes the continuous measurement of ammonia in the exhaust gas. Official approval of the equipment is therefore unnecessary [435], [496]. The equipment Opsis AR 602 Z for NH_3 operates in situ as an NDUV single-beam photometer with radiation source and receiver. The absorption spectrum is determined in certain wavelength ranges of the UV (differential optical absorption spectroscopy). The smallest measurement range checked was 0 – 20 mg/m^3. The detection limit is ca. 0.5 mg/m^3.

The Mipan equipment of Siemens is based on absorption of electromagnetic radiation in the microwave range (microwave process gas analyzer). The method is suitable for gases with a permanent dipole moment. The equipment uses extractive sampling. The smallest measurement range checked was 0 – 15.4 mg/m^3, and the detection limit is ca. 0.2 mg/m^3.

6.9. Measurement of Gaseous Organic Compounds

TA Luft and 17th BImSchV regulations impose emission limits on ca. 150 organic substances. The regulations refer not only to individual compounds, but also groups of substances such as polychlorinated dibenzodioxins (PCDD), polychlorinated dibenzofurans (PCDF), and polychlorinated biphenyls (PCB). Almost all installations, including domestic heating, traffic, commerce and industry, can be sources of organic substances.

6.9.1. *Sampling*

The recommendations in Section Sampling regarding velocity-proportional sampling, heating of the probe, construction materials, etc., also apply here. In addition, chemical changes to organic compounds during sampling due to heat, oxidation, nitration, chlorination, etc. must be prevented. As a rule, the substances must be collected at low temperature. Therefore, the sampled gas should be cooled during sampling by a heat exchanger or by adding purified air or nitrogen to reduce its temperature by dilution. An aqueous condensate is usually formed on cooling. Dust is removed from the sampled gas by a filter. For high-boiling substances such as PCDD/F, PAH, and PCB, the dust contains components that must be analyzed. Here, both gaseous and solid phases must be collected and analyzed to give the total figure. The relative proportion of gaseous and solid materials in the total sample depends on the exhaust gas temperature and sampling conditions. The gas can be collected in sample tubes, or in absorption apparatus with wash bottles or impingers. Solid adsorbents such as active carbon, silica gel, Florisil, resins, or various gas chromatographic media are also used. Depending on the detection limit or emission limit value, the collection apparatus must handle between a few dm^3 and 20 m^3 of sampled exhaust gas, and the sampling time can be up to several hours.

6.9.2. *Measurement of Total-C*

The TA Luft and 17th BImSchV Regulations state that volatile organic substances should be measured and recorded as total carbon.

Discontinuous Measurement. The silica gel method of VDI 3481, Sheet 2 [497] is a manual analytical method. The sampled gas is passed via a sampling probe (sometimes heated) through two adsorption tubes in series packed with silica gel.

The organic substances are adsorbed, though this may not be quantitative in some cases (i.e., CH_4, C_2H_6, C_2H_4, C_2H_2, C_3H_8, C_3H_6, C_3H_4, C_4H_{10}, C_4H_8, C_4H_6, C_5H_{12}, CH_2Cl_2, C_2H_3Cl, C_2H_5OH). Desorption is carried out in a stream of oxygen at elevated temperature followed by combustion to form CO_2, which is determined titrimetrically (acidimetric back-titration of barium hydroxide solution after precipitation of barium carbonate) or coulometrically (neutralization of a barium hydroxide solution). As this method does not adequately measure substances with very low boiling points, discrepancies with other methods can occur, depending on the composition of the exhaust gas. Additional gas chromatographic measurements are advisable. With water vapor concentrations of >20 g/m^3 (dew point ca. 20 °C) the adsorption may no longer proceed quantitatively, and the temperature of the sampled gas should not exceed 25 °C prior to the first sorption stage.

The relative detection limit for the titrimetric determination is 17 mg C/m^3, and for coulometric determination 2 mg C/m^3. When using the silica gel method, even at high temperatures and moisture contents, a condensate collecting vessel or a cooler with a condensate collecting vessel is fitted in front of the adsorption tubes [498]. The condensate must then also be analyzed, as it may contain some of the organic compounds. The concentration of CO_2 in the exhaust gas should be low, as it can dissolve in the condensate and lead to false results.

Continuous Methods. Continuous measurement of total-C concentration is usually carried out with flame ionization detectors (FID). These are described in VDI 3481, Sheets 1 and 2 [499], [500]. The limits of application of the FID process and a comparison with other methods for determining the carbon contents of exhaust gases are discussed in VDI 3481, Sheet 6 [501].

In the flame ionization detector, organically bonded carbon is ionized in a hydrogen flame. The ionic current produced in an electric field is amplified and displayed. It is proportional, over a wide range, to the number of carbon atoms introduced into the flame per unit time. The structure of the molecule (e.g., single and double bonds, number and nature of substituted atoms, chain length, or ring structure) considerably influences the oxidation behavior of the carbon and hence the magnitude of the detector signal. Thus, organic compounds with heteroatoms (e.g., N, O, S, or Cl) are generally detected with considerably lower sensitivity than hydrocarbons with the same number of carbon atoms per molecule.

The varying sensitivities to the various organic compounds are expressed as response factors. These are equipment-specific, depending, for example, on jet shape, electrodes, combustion space, and combustion air mixing, and must not be assumed to apply to other FID equipment.

A schematic diagram of an FID is given in Figure 31. The flame requires fuel gas (hydrogen or hydrogen-containing mixtures) and combustion air free of organic substances. The fuel gas and sample gas are mixed before they enter the flame. The combustion air is fed to the flame separately. The flow of combustion air is adjusted so that the flame burns steadily, while at the same time the dew point is kept as low as possible by dilution of the fuel gas, preventing undesired condensation in the exhaust gas duct of the detector. As the pressure and the volume flow rate at the FID affect the measured value, these must not be altered after calibration. Depending on the sensitivity (measurement range) and equipment type, quality requirements for the fuel gas, combustion air, test gas, and composition of the sampled gas (hydrogen/oxygen cross-sensitivity) vary.

An overview of equipment is given in Table 17. Monitoring limit values for total-C specified in 17th BImSchV (10/20 mg C/m^3) requires a measurement range of 0 – 30 mg/m^3.

* Heat evolution.

One type of equipment operates on the principle of heat evolution. Catalytic oxidation of combustible components of the gas produces heat which is detected by temperature measurement. There is cross-sensitivity towards CO. The catalysts are poisoned by halogen, lead, and silicon compounds.

6.9.3. *Chlorinated Hydrocarbons*

The various chlorinated organic compounds that can occur in emissions can exist as gases, vapors, solids, materials adsorbed on solids, or as mixtures thereof. Therefore, different sampling and analysis methods are required, depending on the boiling points of the individual compounds and the exhaust gas temperature. Boiling ranges of halogenated compounds of Classes I – III (taken from Subparagraph 3.1.7 of TA Luft) are illustrated graphically in Figure 32 [502]. The boiling ranges of PCDD, PCDF, and PCB compounds are shown for comparison.

Figure 32. Boiling point ranges of organic compounds (taken from TA Luft)

The high-boiling PCDDs and PCDFs have been thoroughly investigated owing to their environmental implications. Emission measurement methods are described in VDI 3499. A CEN Standard is in preparation, and investigations into PCBs are also in progress. The chlorobenzenes and chlorophenols in the middle boiling range have only been investigated individually from the point of view of emissions. This group of substances can be determined by the sampling and analysis methods described for high-boiling substances. However, there have been no systematic investigations of any significance.

6.9.3.1. *Polychlorinated Dibenzodioxins and Polychlorinated Dibenzofurans (PCDD/F)*

PCDDs and PCDFs are emitted at exhaust gas temperatures between 50 and 400 °C, depending on the design and exhaust gas purification technology of the plant. In this temperature range, the compounds exist in gaseous, solid, and adsorbed form, depending on boiling point. Because volume flow rates of exhaust gases from industrial plants are very high, analysis usually has to be based on extractive sampling, and, because of the presence of the particle phase, the sampling must be isokinetic, using a measurement grid for reasons of representativity. For limit values of ≤0.1 ng/m^3 as a toxicity equivalent, sampling volume rates of 10 – 20 m^3/h are necessary. To ensure mild collection of organic compounds, sampling must take place at a low temperature (if possible <50 °C). At higher temperatures, the sample gas stream must be cooled by dilution with air or by cooling.

The dilution method is described in VDI 3499, Sheet 1 [503]. Cooling is carried out by adding dried air to the gas stream. This prevents the temperature from falling below the dew point of water and causing condensation. The design of the sampling equipment is illustrated in Figure 33.

Figure 33. Schematic diagram of a sampling system using the dilution method

a) Probe; b) Heated suction tube (thermostated); c) Mixing tube; d) Sample filter; e) Solid adsorbent; f) Gas meter; g) Cooling air filter; h) Drying tower

The gas is sampled isokinetically by a probe heated to the temperature of the exhaust gas. The sampled gas stream is cooled to below 50 °C by adding dried, filtered air. The diluted exhaust gas is then passed through a filter which traps the solids and the condensed fraction of organic compounds, and the fraction adsorbed on the particles. The PCDDs and PCDFs are collected on the filter at ca. 40 °C almost quantitatively. A solid sorbent such as Florisil, XAD adsorber resin, Porapak, or PU foam, can be included to ensure complete filtration. Alternatively, the above system can be replaced by a flat filter with PU foam as the collecting phase, as is commonly used for the measurement of PCDD and PCDF as atmospheric pollutants.

The sampling system described in Sheets 2 – 4 involves condensation methods with direct cooling [504-506].

Sheet 2. Condensation – adsorption method with filter
Sheet 3. Condensation method, cooled sampling probe
Sheet 4. Condensation method with polyurethane foam for adsorption

In the condensation method of Sheet 3 the hot exhaust gas is cooled as it is withdrawn through the water-cooled probe, and the condensate formed is collected in a cooled separator. Filtration through a solid medium is thus avoided. The sampled gas is then passed through two parallel impinger lines filled with organic solvent, or through a solid adsorbent. The sampling apparatus is shown schematically in Figure 34.

In the method of Sheet 4, PU foam is used as an additional adsorbent. For inclusion of this sampling method in the CEN Guideline, a solid filter is planned prior to the last absorption or adsorption stage.

The first analytic step is extraction of the organic compounds from the collecting phase. For example, in the dilution method, a sampling filter, and, if necessary, a solid absorbent (XAD-2, Florisil, Porapak PS, and polyurethane foam) are used as collecting devices. For the solvent extraction stage, the whole glass fiber filter including loose dust particles is transferred to an extraction thimble. For isomer-specific measurement of the PCDD/F, ca. 5 ng of the following ^{13}C-

labelled standards (one per isomer group) added before extraction

^{13}C-2,3,7,8-tetraCDD/F, ^{13}C-1,2,3,7,8-pentaCDD/F, ^{13}C-1,2,3,7,8,9-hexaCDD, ^{13}C-1,2,3,4,7,8-hexaCDF, ^{13}C-1,2,3,4,6,7,8-heptaCDD/F, ^{13}C-1,2,3,4,6,7,8,9-octaCDD/F.

Extraction with toluene is then carried out in a Soxhlet apparatus for at least 20 h. The toluene extract is reduced to ca. 10 mL in a rotary evaporator at ca. 70 mbar and a bath temperature of ca. 45 °C. The adsorbents XAD-2 and Porapak PS are also extracted with toluene in a Soxhlet apparatus, for at least 20 h. Florisil is eluted with dichloromethane in a glass column. Before further treatment, the extract or eluate is reduced to ca. 5 mL under a controlled vacuum (70 mbar, 45 °C). The extracts can be combined for determination of total PCDD/F, or treated separately. Sample treatment is illustrated in Figure 35.

The ^{13}C-labelled standards are added to the fraction which experience shows is likely to have the higher PCDD/F content. This is either the filter (VDI 3499, Sheet 1) or the condensate (Sheet 2). The extracts are transferred to a column packed with 50 g aluminum oxide and 10 g sodium sulfate, which is eluted with benzene and then with hexane/dichloromethane (98 : 2). This eluate is collected and checked to ensure that at least 60 % of the ^{13}C-2,3,7,8-TCDD is present. The PCDD/F is then eluted with 200 mL hexane/dichloromethane (1 : 1). The eluate is reduced to ca. 2 mL under vacuum, transferred to a mixed column, and eluted with 250 mL hexane. This eluate is reduced to ca. 5 mL, and then chromatographed on a column of Bio-Beads (PCDD/F fraction 120 – 180 mL). The solvent is removed from this fraction under vacuum. The residue is taken up in a solution of 5 ng (or less) $^{13}C_6$-1,2,3,4-TCDD in 100 µL benzene, reduced if necessary in a stream of nitrogen to 30 – 50 µL, and analyzed by GC/MS. The quantitative evaluation is based on the added ^{13}C-labelled standard, identical response factors for all PCDD/F isomers being assumed for all degrees of chlorination. The analysis is carried out “isomer-specifically” for the 2,3,7,8-substituted PCDD/F. The capillary columns are charged with Silar C or an equivalent phase such as Sil 88, SP 2330, or SP 2331. Coupling with the mass spectrometer can be carried out either direct or open. Analysis is by mass fragmentography, with at least two masses being recorded both for the tetra- to octa-CDD/CDF and for the ^{13}C-labelled standard. The absolute detection limit depends on the mass spectrometer used and the amount of material injected, and is normally ca. 0.001 – 0.1 ng per individual isomer and sample. For a gas sample volume of ca. 20 m^3, the detection limit is 0.00005 – 0.005 ng/m^3 for a single isomer.

Figure 35. Scheme of sample preparation for PCDD/F

6.9.3.2. *Polychlorinated Biphenyls*

Sampling of PCB can be performed by the same technique as used for PCDD/F. However, there is at present no mandatory guideline with proven parameters. The stages of the analysis are the same as those used in dioxin analysis, the choice of separation and extraction materials being based on the specific properties of PCB (polarity, solution properties). Before extraction of the solid filter (flat filter/PU foam, see VDI 3499, Sheet 1) or of the condensate (VDI 3499, Sheet 3) with toluene, internal standards (^{13}C-labelled for subsequent GC – MS analysis or PCB 28 and PCB 202 for subsequent GC – ECD analysis) are added.

After addition of 6 mL decane, the extract is reduced with the aid of a rotary evaporator and charged to the mixed column (see VDI 3499 and VDI 3498). It is eluted with 250 mL hexane, and the eluate is then reduced to 6 mL and charged to a alumina column. This is then eluted with 60 mL *n*-hexane, 90 mL toluene, and 250 mL *n*-hexane/dichloromethane (1 : 1) [507], [508]. The toluene contains the PCB compounds and the hexane – dichloromethane mixture the PCDD/F compounds. The fractions can be purified if necessary by a further cleanup with, e.g., Florisil or HPLC. A labelled standard is then added, e.g., for PCB, $^{13}C_{12}$-2,2′,4,5,5′-pentachlorobiphenyl, and, for PCDD/F, $^{13}C_6$-1,2,3,4-tetrachlorodibenzodioxin. It is then reduced to a final volume of 10 – 20 µL, and analyzed by GC – MS. The relative detection limit for the total content of PCB is 10 – 20 ng/m^3. For the individual components it is ca. 1 – 2 ng/m^3.

6.9.3.3. *Chlorobenzenes and Chlorophenols*

Sampling of chlorinated benzenes and phenols can in principle be carried out by the same methods as those for PCDD/F and PCB. There is no guideline with approved method parameters. Also, individual tests should be carried out to determine to what extent the more volatile mono- and dichlorocompounds are quantitatively recovered. Suitable collecting phases include solid filters, PU foam, methoxyethanol, and adsorber resins. Another possibility is absorption in cold solvents (e.g., methyldiglycol), as described in the draft version of VDI 2457, Sheet 2 [509].

Chlorobenzene. Toluene is used as an extraction medium for separating chlorobenzenes and chlorophenols from the collecting phase. The toluene extract is reduced to a few milliliter, and chromatographed on alumina. Elution is then carried out with hexane/dichloromethane (98 : 2), and this fraction is again reduced in volume. Analysis for chlorobenzenes is carried out, for example, by GC – ECD or GC – MS. The quantification of the chlorobenzenes is carried out externally using a mixture of di- to hexachlorobenzenes. Analysis can also be carried out with ^{13}C-labelled standards, using one standard for each degree of chlorination. The relative detection limit is ca. 1 ng/m^3 for each component.

Chlorophenols. The chlorophenols are determined by extracting the toluene extract with K_2CO_3 solution. Acetic anhydride is added, the samples are agitated, and the chlorophenol acetates are then extracted with hexane. The hexane extract is dried over Na_2SO_4, and analyzed by GC/ECD or GC/MS. Quantification of the chlorophenols is carried out externally using a mixture of di- to pentachlorophenols derivatized under the same conditions. Alternatively, ^{13}C-labelled standards can be used.

6.9.3.4. *Volatile Chlorinated Hydrocarbons*

Volatile chlorinated hydrocarbons (VCH) such as trichloroethane, trichloroethylene, tetrachloroethane, and tetrachloroethylene are used in industrial surface treatment, chemical cleaning, and solvent extraction. Limit values are imposed by 2nd BImSchV on emissions of the above VCHs and dichloromethane [425]. The use of trichloroethane is now prohibited in some cases.

Measurement of emissions is described in the VDI 2457, Sheets 2 – 4 of 1974 – 1976 for 1,1,1-trichloroethane, trichloroethene, and tetrachloroethene. They are absorbed in a liquid sorbent and determined by gas chromatography. However, in some cases the detection limit is relatively high.

Sampling and analysis are therefore now carried out by a method based on that used for ambient air pollution measurement [510], [511]. Small test tubes packed with activated carbon are used to collect the sample, and desorption is then carried out with solvents or by heating. The sampling itself is carried out with quartz probes provided with dust filters, if necessary heated to the temperature of the exhaust gas. With higher water vapor contents, a condensate trap follows the dust filter. The condensate is also analyzed for VCHs by gas chromatography. Another solid sorbent for pollutants is 2,6-divinylbenzene-*p*-phenylene oxide polymer (Tenax TA) [512]. The VCHs can be desorbed for gas chromatographic analysis and recondensed in a cooled container. Detection is by ECD or mass spectrometry. Another method is absorption in a cold solvent [509].

6.9.3.5. *Chlorofluorocarbons*

The regulation 2nd BImSchV referred to in Section Volatile Chlorinated Hydrocarbons above also imposes limits on the emission of chlorofluorocarbons (CFCs) the only permitted CFCs being 1,1,2,2-tetrachloro-1,2-difluoroethane (R-112), 1,1,2-trichloro-1,2,2-trifluoroethane (R-113), and trichlorofluoromethane (R-11). Sampling is performed by the method described in Section Volatile Chlorinated Hydrocarbons, the substance being adsorbed on, e.g., activated carbon. With low-point components, gas collecting tubes can be used. Analysis is carried out by GC/ECD.

6.9.4. ***Hydrocarbons***

TA Luft imposes emission limits on a number of hydrocarbons, depending on the substance group and mass flow rate. Total emission concentrations of 20 – 150 mg/m^3 are permitted, depending on the substance classification. Substances such as benzene, acrylonitrile, or polycyclic aromatic hydrocarbons, are controlled separately in Subparagraph 2.3 of TA Luft.

Polycyclic Aromatic Hydrocarbons. Polycyclic aromatic hydrocarbons (PAH) are present in many natural materials, for example, mineral oil. PAH structures exist in coal, but the compounds themselves are only formed after chemical transformation. In industrial processes, unreacted PAH residues and newly formed PAH are emitted during the incomplete combustion or pyrolysis of organic materials, especially fossil fuels. Some polycyclic aromatic hydrocarbons, especially tetracyclic to hexacyclic compounds, have a mutagenic and/or carcinogenic effect on human and animal organisms. A limit of 0.1 mg/m^3 is imposed on benz[*a*]pyrene and dibenz[*a, h*]anthracene by TA Luft. VDI 3873, Sheet 1 describes a method of measurement for use in industrial and commercial plants [513]. The sampling method used is the dilution process described in VDI 3499 (see Section Polychlorinated Dibenzodioxins and Polychlorinated Dibenzofurans (PCDD/F)). The four- to seven-ring PAH compounds have approximately the same boiling range as PCDD/F. They therefore occur in exhaust gases as gases, solids, and materials adsorbed on particles. The method of VDI 3873, Sheet 1 can deal with all states of aggregation. The four- to seven-ring compounds are quantitatively collected on a filter. The more volatile PAH compounds with two or three rings can be recovered by a downstream solid sorbent (e.g., Porapak PS). It is possible to collect PAH, PCDD/F, and PCB at the same time. The sampling times (collecting times) should not exceed ca. 2 h to ensure that the PAH profile remains the same, because some PAH compounds are very reactive. A detection limit of ca. 10 ng per component can be achieved. With a sample volume of 5 m^3 a relative detection limit of 2 ng/m^3 per component can be attained. The exposed filter is extracted with toluene for 30 min after adding the internal standard. The sample preparation scheme is illustrated in Figure 36. A detailed description can be found in VDI 3873, Sheet 1. Analysis is then carried out by capillary GC.

Figure 36. Scheme of sample preparation for PAH

Aromatic and Volatile Hydrocarbons. The sampling technique for aromatic hydrocarbons (benzene, toluene, xylene, and ethylbenzene: BTXE) is similar to that used for pollution measurement described in Section Volatile Chlorinated Hydrocarbons. The most important collecting phases used are activated carbon, Tenax, and cold solvents [510], [511]. Materials are desorbed from activated carbon mainly with solvents [514] or by thermal methods. Identification is by GC – FID or sometimes GC – MS. If condensate is formed during sampling, this must also be analyzed. With a sampling volume of 20 L, the detection limit is 5 µg/m^3 per component. The Guideline VDI 2457, Sheet 1, which describes the fundamental principles of sampling and determination of organic compounds by gas chromatography, should be consulted [515]. The method of absorption in nitrobenzene described in VDI 2457, Sheet 5 is less suitable because of the high detection limits and various cross-sensitivity effects [516].

Volatile organic compounds (VOC) such as aliphatic, cyclophatic, and aromatic hydrocarbons and solvents can be determined by the methods given for BTXE or VCH compounds. Activated carbon or other solid sorbents are mainly used.

1,3-Butadiene. Emissions of 1,3-butadiene, like those of acrylonitrile, must not exceed 5 mg/m^3 according to Subparagraph 2.3 of TA Luft. The Guideline VDI 3953 describes a measurement method by adsorption on activated carbon and desorption with CS_2 [524]. Gas chromatographic analysis is based on the GC –FID head space technique (vapor space analysis). The determination limit is 0.2 mg/m^3 with a sampled gas volume of 30 L. The limited storage time of the samples must be borne in mind.

6.9.5. *Other Compounds*

Phenol and Cresols. Phenol and the cresols can be collected on silica gel using the sampling arrangement described in Section Volatile Chlorinated Hydrocarbons for active carbon. Identification can be made by HPLC with a fluorescence detector. With a sampled gas volume of ca. 30 L, a detection limit of ca. 1 µg/m^3 is achieved.

Amines. Aliphatic amines such as methylamine, dimethylamine, ethylamine, propylamine, butylamine, and hexylamine can be quantitatively determined, especially in exhaust air, by the method described in VDI 2467 for ambient air pollution measurement [517]. The amines are dissolved as alkylammonium chlorides in dilute hydrochloric acid, and are then reacted to form dinitrophenylamines. Determination is by HPLC, with UV absorption analysis. Aromatic amines can be sampled with silica gel tubes and determined by HPLC – UV. Detection limits, e.g., in the case of 2-naphthylamine and toluidine, are ca. 5 µg/m^3.

Aldehydes. Short-chain aldehydes are formed by the incomplete combustion of hydrocarbons or alcohols, e.g., in internal combustion engines including diesel engines.

A method of measuring these emissions is described in the VDI 3862, Sheet 1 [518]. Aliphatic C_1 – C_3 aldehydes are absorbed in solutions by the MBTH (3-methyl-2-benzothiazolinone hydrazone) method, and determined photometrically. The determination limit is 0.05 mg/m^3 if the volume of exhaust gas sampled is 25 L. If SO_2 is present at concentrations of >30 mg/m^3, the method is unsuitable because of interference effects.

In Sheet 2 (in preparation) of VDI 3862 the determination of long-chain and aromatic aldehydes and ketones is described [519]. These substances are reacted with 2,4-dinitrophenylhydrazine (DNPH method) to give the hydrazone and determined as individual components. Sampling is carried out with wash bottles containing acetonitrile to dissolve the hydrazine. The absorption solution is directly chromatographed without further treatment. Determination is by HPLC with UV absorption analysis.

Sheet 3 of the VDI 3862 (in preparation) describes sampling with the aid of DNPH dissolved in hydrochloric acid solution [520]. The hydrazones are extracted with carbon tetrachloride, the organic phase is chromatographed using HPLC, and analysis is performed by UV absorption. Depending on the substance, detection limits between 2 and 100 µg/m^3 have been quoted for a sampled volume of 50 L. A disadvantage is that the samples can be stored for a short time only.

Acrylonitrile. Three methods for the determination of acrylonitrile are described in VDI 3863, Sheets 1 – 3 [521-523].

Sheet 1: Sampling by a gas sample container. The detection limit with a flame ionization detector (FID) is 0.5 mg/m^3. With a phosphorus – nitrogen detector (PND), the limit is 0.05 mg/m^3. The samples can be stored only briefly. With high water vapor contents, the methods of Sheets 2 and 3 are used.

Sheet 2: Sampling in cold solvents, detection limit with 15 L sampled volume using FID 0.2 mg/m^3, or using PND 0.05 mg/m^3. Samples can be stored only briefly.

Sheet 3: Sampling on activated carbon, desorption with dimethylformamide (DMF), detection limit 12 µg/m^3 with 50 L sampled volume. GC with column switching and two FIDs.

All sampling equipment is fitted with a sampling probe and solid filter (heated if necessary).

Vinyl Chloride. The determination of vinyl chloride by gas chromatography of samples collected in gas sample containers is described in the Guideline VDI 3493, Sheet 1, of Nov. 1982 [525]. Analysis is by GC – FID, the determination limit being 0.3 mg/m^3. Subparagraph 2.3 of TA Luft imposes an emission limit value of 5 mg/m^3. By adapting the method of VDI 3494, Sheets 1 and 2, for determining vinyl chloride ambient air pollution by adsorption on activated carbon, it should be possible to achieve improved sensitivity [526], [527].

6.10. Measurement of Odor Emissions

Odor emissions can be produced in many industries, e.g., cocoa, coffee, and tobacco processing, fish production and processing, rubber production and processing, and the chemical industry. The aims of the measurement technique are to determine the odor intensity (based on determination of the odor threshold), to estimate nuisance potential, to estimate the effectiveness of techniques of odor emission reduction (crude/purified gas), and to establish data to enable spreading rates to be calculated and odor pollution to be forecast. Odors are determined using the human nose as a sensor (olfactometry). Olfactometry consists of the controlled presentation of odoriphores (odoriferous substances) and the assessment of the sensations which these produce in human subjects. An odor sensation can be caused even when the concentration of an odoriphore is less than the limit of detection by chemical or physical methods. The qualitative and quantitative assessment of mixtures with a large number of components is difficult. Even if analysis is possible, there may be no connection between this and the odor sensation.

The concentration of the odoriphore in the gas sample (single substance or mixture of substances) under investigation is determined by diluting with neutral air until the odor threshold is reached. One odor unit (OU) is the quantity of odoriphore which when uniformly distributed in 1 m^3 of neutral air produces an odor sensation in accordance with the definition of the odor threshold. The unit of odoriphore concentration is one odor unit per unit volume (OU/m^3). The odor threshold is the concentration of a substance or mixture of substances that gives an odor sensation in 50 % of a statistical sample of test subjects. The fundamental principles of odor threshold determination are described in the VDI 3881, Sheet 1 [528]. Olfactometers are used for measurement. A gas sample containing an odoriphore is diluted with various amounts of neutral air in a controlled manner and submitted to test subjects for odor testing.

Sampling can be dynamic or static. In dynamic sampling, a stream of exhaust gas or exhaust air is continuously removed. The olfactometer is attached by a T-piece to the sample line, so that a test volume can be fed into the olfactomer as required. The scheme for dynamic sampling is illustrated in Figure 37.

Figure 37. Dynamic sampling

a) Sampling probe; b) Dust filter (if necessary); c) Air addition for dilution (if necessary); d) Pipeline for gas samples; e) Excess to exhaust air; f) To the olfactometer

In static sampling, the sample of odoriferous substance is charged into a container, transported to the olfactomer, and connected to it for the experiment. Possible methods of static sampling are shown schematically in Figure 38 [529]. If there is a possibility that water or other substances in the sample could condense inside the bag, the sample should be diluted. In this case, the sample bag is filled with a definite amount of odor-free air in an apparatus as shown in Figure 38. A definite amount of the test gas is then added. The dynamic sampling method is advantageous for constant emission condition because of the short time delay between sampling and analysis. The method is not suitable if concentrations change rapidly, as the sampled material changes during the course of an individual measurement, and there can then be a wide distribution of measured values.

Figure 38. Various methods of static sampling

A) Bag filling by suction pump; B) Bag filling by pressure pump; C) Bag filling by suction pump with additional dilution with filtered air

a) Sampling probe; b) Valve; c) Bag; d) Bag container; e) Pump; f) Activated carbon filter

With static sampling of varying concentrations, a representative mean value over the sampling time is obtained. Evaluation of the results is described in [528], [530]. Various types of olfactometer are described in [531]. The parameters of the method and an example of an odor measurement record are given in [532].

7. Separation and Purification

Eberhard Schmidt, Torsten Schmidt, Theo Pilhofer, Helmut Krill, Harald Menig, Stephan Schirz, Helmut Pollack

7.1. Separation of Solid and Liquid Particles from Gases [533-541] (see also ⟶ Dust Separation)

7.1.1. *Introduction*

Many industrial processes inevitably generate particles entrained by a carrier gas. These particles may be solid (dust) or liquid (droplets or mist). As a rule, the particles must be separated from the transporting gas, either because they are the desired product or because they are an undesirable emission. Product recovery by dust separation has been practiced long and intensively in process engineering. The importance of emission control has grown tremendously in the last two decades, because of rapid increases in industrial production, and better knowledge of potential hazards and harmful effects.

Dust collection methods used in practice can be classified as inertial and centrifugal separation (gas cyclones), wet collection (scrubbers), filtration (deep-bed filters, surface filters, and granular-bed separators), and electrostatic collection (precipitators). All of these collectors separate particles from gas by a common principle: forces acting on the particles cause them to enter regions from which the gas cannot transport them away. These regions may be the inner wall of a cyclone, the droplet surface in a scrubber, the fiber or grain surface in a filter, or the collecting electrode in a precipitator.

One difficulty in selecting and designing separation processes is that the size distribution of the particles to be collected generally extends over a wide range, from <0.1 µm to >100 µm. The knowledge about the dependence of the operational characteristics of each separator on particle size distribution is very important and is discussed widely.

7.1.2. *Characterization of Particle Separation*

To evaluate dust collection equipment, both the energy consumption (or pressure drop Δp) and the collection efficiency must be determined. The latter can be found by integration techniques (for the totality of particles) or differential methods (for each particle size fraction).

The overall collection efficiency *E*, also known as the total or cumulative collection efficiency, is given by

$$E = \frac{\dot{M}_c}{\dot{M}_e} = \frac{\dot{V}_e c_e - \dot{V}_f c_f}{\dot{V}_e c_e} = 1 - P \tag{1}$$

where *E* is collection efficiency, $\dot{M}$ is mass flow rate of particles, $\dot{V}$ is volume flow rate of gas, *c* is particle concentration, and *P* is penetration. The subscript c stands for collected (coarse), e for entry, and f for penetrating (fine).

Note that if a collection device is rated in terms of overall collection efficiency, this quantity depends not only on the equipment design and operating conditions, but also on the type of dust and, especially, the particle-size distribution. The stated overall collection efficiency or overall penetration thus always refers to a particular case. A more useful and informative measure is the fractional collection efficiency *T* (*x*), which measures collection as a function of particle size *x*:

$$T(x) = \frac{\mathrm{d}\,\dot{M}_c(x)}{\mathrm{d}\,\dot{M}_e(x)} = 1 - \frac{\dot{V}_f \mathrm{d}\,c_f(x)}{\dot{V}_e \mathrm{d}\,c_e(x)} \tag{2}$$

With $\dot{V}_f = \dot{V}_e$ and particle size distribution *q*:

$$T(x) = 1 - \frac{P_{q_f}(x)}{q_e(x)} = \frac{E_{q_c}(x)}{q_e(x)} \tag{3}$$

The cut size x_t is the particle size at which a given fractional collection efficiency *T* is achieved. A value of 50 % is often used ($x_{50,t}$).

7.1.3. *Gas Cyclones*

7.1.3.1. *Mode of Operation and Basic Designs*

The simplest way to separate particles from gases is to allow them to settle out in so-called gravity settlers into zones of low gas velocity. Because this method is technically feasible only for coarse particles that are significantly larger than 100 µm, gravity settlers now have negligible importance and are not discussed here.

Collection by means of centrifugal forces is much more efficient than simple gravity separation, and this led to the development of centrifugal collectors. Because of their simple design, reliable operation, small space requirement, and low cost, gas cyclones are used widely in many branches of industry. They are frequently employed in material recovery from gas recycle systems, pneumatic conveying, and other areas. They are often used as first-stage collectors. Cyclones can be operated at pressures of 1 kPa to 10 MPa and temperatures exceeding 1200 °C. The advantages of cyclones over other collectors are offset by the fact that they are less efficient collectors for particles below ca. 1 – 5 µm in size.

Figure 39 shows the most common type of cyclone with flow reversal. The gas path is designed to impart a twist to the particle-laden gas entering the rotationally symmetrical apparatus. A turbulent, three-dimensional, rotational flow is produced. In the separating chamber spiral, downward flow takes place at larger radii. Flow is then reversed, and the gas spirals upward at smaller radii, and reaches the exit duct (vortex finder). The particles entrained in the revolving gas stream experience centrifugal forces hundreds to thousands of times greater than the force of gravity. Thus, the larger particles migrate outward to the cyclone wall, where they collect as strands; they are carried down the tapered body and out of the separating chamber by boundary-layer flow. The conical shield, often built into the bottom of the tapered body, prevents already collected material from being reentrained. The particles that are not collected are carried inward by the gas flow and removed through the exit duct.

Figure 39. Schematic of a reverse-flow cyclone

A) Vertical section; B) Top view

a) Exit duct; b) Separating chamber; c) Gas flow pattern; d) Conical shield; e) Dust hopper; f) Dust; g) Lock

Cyclones vary in the form of the swirl-producing inlet (tangential, axial with swirl vanes), the shape of the separating chamber (cylindrical, conical), the design of the exit duct, and their dimensions. Diameters range from 0.02 m to 5 m and flow rates from 1 to 100 000 m^3/h.

7.1.3.2. *Collection Efficiency and Pressure Drop*

Important parameters in cyclone design and operation are the fractional collection efficiency $T(x)$ and the energy consumption, measured in terms of the pressure drop Δp.

Several models have been devised for the approximate calculation of collection efficiency at low dust loads. They describe the flow field in more or less simplified terms. The separation-zone model is now employed widely because of its simplicity and ease of use. However, this approach does not give the complete fractional efficiency curve; only a critical particle diameter x_{cr} can be calculated. According to this concept, all particles whose diameter x is less than x_{cr} pass through the device; larger particles are collected.

In theory, the fractional efficiency curve jumps from 0 to 1 at x_{cr}. It is more reasonable to assume that x_{cr} corresponds to the median diameter $x_{50,t}$ of the real separation function $T(x)$, i.e., the 50 % value on the effective S-shaped fractional efficiency curve. Based on experimental results the suggestion has been made that the actual cut diameter can be estimated as $x_{50,t} \approx 1.3 \cdot x_{cr}$.

In a more detailed approach, particle motion is treated as a process in which diffusional particle transport is superimposed on a predetermined motion. Particle flux calculations are based on a modified flow field. The advantage of this model is that the complete fractional efficiency curve can be obtained.

At higher particle concentration (> 10 g/m^3), additional collection mechanisms contribute to particle separation. By analogy with pneumatic conveying a limiting dust load c_m is proposed. The excess particle mass cannot be transported by the gas and is accelerated to the wall immediately after entering the cyclone; the particles move down into the dust trap in the form of a strand. Along with particle collection due to excess loading, agglomeration of small particles with large ones can be assumed to occur at high particle concentration; this also improves overall collection efficiency.

The total pressure drop of a cyclone consists of pressure losses in the inlet, separating chamber, and exit duct; it is usually calculated as

$$\Delta p = (\xi_{\text{inlet}} + \xi_{\text{separator}} + \xi_{\text{exit}}) \cdot \frac{\varrho_f v_i^2}{2}$$

where ξ is the pressure drop coefficient, ϱ_f is the gas density, and v_i is the axial velocity in the exit duct. Experience has shown that the pressure drop in the exit duct accounts for as much as 90 % of the total cyclone pressure drop. Typical values for Δp are in the range of 500 – 2000 Pa.

7.1.3.3. *Operational Characteristics*

The collection performance of a cyclone depends chiefly on its geometry, gas throughput, inlet gas concentration, and properties of the material to be separated. For example, the increase in gas viscosity when the temperature is raised decreases performance. If the exit-duct diameter or inlet cross section is diminished, the tangential velocity component at the exit-duct radius increases, so that a greater centrifugal force acts on the particles. As a result, the cut size $x_{50,t}$ decreases and particle collection improves. Collection efficiency is also improved if the volume flow rate through the cyclone increases. Theoretically the cut size varies according to $\dot{V}^{-0.5}$.

When the tangential velocity in the cyclone increases, however, the pressure drop Δp also increases. To achieve good collection performance and acceptable energy consumption in cleaning gases with high flow rates, several small cyclones connected in parallel are preferable to a large cyclone because the reduction in cyclone diameter shifts the cut size toward smaller particle sizes. Figure 40 presents typical fractional efficiency curves for three cyclones with different diameters but the same pressure drop. If geometrically similar cyclones are assumed and Δp is constant, the result for cleaning a gas with a given flow rate $\dot{V}$ is that the cut size for n cyclones in parallel is proportional to $n^{-0.25}$.

Figure 40. Fractional efficiency curves for cyclones of varying diameter d at a constant pressure drop

$\dot{V}$ = volume gas flow rate

7.1.4. *Wet Scrubbers*

7.1.4.1. *Mode of Operation and Basic Designs*

In wet collectors, both particulate and gaseous components can be separated from the carrier gas.

Even very fine particles (<0.1 µm) can be collected in scrubbers. The particles are brought into contact with a scrubbing liquor and are removed from the gas stream in bound form as a slurry, which must be subjected to wastewater treatment or liquor recycling. In most scrubbers the scrubbing liquor is in droplet form. The first operation can, therefore, be regarded as the agglomeration of small solid particles and larger liquid particles. These droplets are readily collected from the gas stream.

The transport step is decisive in separation. Diffusion and condensation can take place, but in general inertial forces appear to dominate. The wettability of the particles does not play a crucial role in binding; wettable particles penetrate the interior of the droplet, while nonwettable particles adhere to the surface.

Efficient dust collection in a scrubber requires separation of the dust-laden droplets in a separator that is either integrated into the scrubber or connected downstream. Because droplet sizes generally range from 1 µm to several hundred micrometers, commercial separators utilize inertial forces to separate droplets from the gas stream. Layers of wire mesh or fabric, stacks of plates, or centrifugal devices are employed.

Scrubbers are relatively easy to adapt to various operating conditions. They are employed mainly when products are to be recovered from a wet phase or when the danger of dust explosion or other hazards forbids dry collection. They have proved suitable chiefly for moderately large-volume gas flow rates (often <30 000 m^3/h). Many scrubber designs are available. However, most designs fall into five basic types, shown in Figure 41. Typical operating data are listed in Table 18.

Table 18. Operating data for scrubbers (see also Figure 41

	Packed-bed scrubber	Ejector venturi scrubber	Self-induced spray scrubber	Rotational scrubber	Venturi scrubber
Cut size, µm*	0.7 – 1.5	0.8 – 0.9	0.6 – 0.9	0.1 – 0.5	0.05 – 0.2
Relative velocity, m/s	1	10 – 25	8 – 20	25 – 70	40 – 150
Pressure drop, kPa	0.2 – 2.5		1.5 – 2.8	0.4 – 1.0	3 – 20
Water consumption, L/m^3	0.05 – 5	5 – 20*		1 – 3*	0.5 – 5
Energy consumption kW · h/1000 m^3	0.2 – 1.5	1.2 – 3	1 – 2	2 – 6	1.5 – 6

* Particle density ϱ_p = 2.42 g/cm^3.

* For each stage.

Figure 41. Basic types of scrubbers

A) Spray tower; B) Ejector venturi scrubber; C) Self-induced spray scrubber; D) Rotational scrubber; E) Venturi scrubber

The spray tower (Fig. 41 A) is the oldest type of scrubber. The dirty gas flows upward through a large tube at a relatively low speed of ca. 1 m/s. The washing fluid is dispersed countercurrent to the gas by spray nozzles mounted at different levels. The dust-laden liquid leaves the bottom of the scrubber. Packings (e.g. glass beads) are sometimes used to improve collection efficiency. The droplet collector can be integrated in the upper region.

The ejector venturi scrubber (Fig. 41 B) is basically a water-jet pump. Water is sprayed into the scrubber at a speed of ca. 25 – 35 m/s and provides a draft for moving the gas, which often attains a flow rate of 10 – 20 m/s. Two successive stages are often used because the collection efficiency of ejector venturi scrubbers is not much higher than that of spray towers.

In self-induced spray scrubbers (Fig. 41 C) the dust-laden gas is fed through the wash fluid. The wash fluid is thus atomized, entrained, and mixed with the gas. This effect is reinforced by a redirecting vane. Entrained, dust-laden fluid

collects inside the scrubber in the collection tank.

In rotational scrubbers (Fig. 41 D), the washing fluid is dispersed radially in the gas by rotating spray nozzles. The gas spirals upward and the dirty water is removed from the bottom of the scrubber. The droplet collector is located downstream.

Venturi scrubbers (Fig. 41 E) have the highest collection efficiency. The gas is accelerated up to 150 m/s in the venturi throat. The washing fluid enters the middle of the throat just in front of its narrowest point or is fed radially into the throat. The liquid is dispersed by the inflowing gas. The dust-laden water droplets are usually separated from the gas in a cyclone.

7.1.4.2. *Collection Efficiency and Pressure Drop*

Development and sizing of scrubbers are often purely empirical because the processes that occur in these complicated pieces of equipment are complex and difficult to simulate with theoretical models. However, the proposed models are quite helpful because they allow clear identification of important parameters and trends.

In most models, the scrubbing liquor is assumed to be in droplet form, and inertial forces are considered crucial for the transport of dust particles to the droplet. The calculation consists of three steps: calculation of single-droplet collection, calculation of the gas volume cleaned by the single droplet, and calculation of the change in dust concentration due to the action of all droplets. Important parameters are the Reynolds number and the inertial parameter (Stokes number). The effort required for the numerical computations is shortened substantially by fitting the equations to experimental values, so that the equation of motion for the droplets need not be solved. For the venturi scrubber, such an equation for the fractional collection efficiency $T(x)$ is given by

$$T(x) = 1 - \exp\left[-\frac{2\,\dot{V}_l d_l \varrho_l v}{55\,\dot{V}_g \mu} \cdot F(\psi, f)\right] \tag{4}$$

where $\dot{V}_l$ is the volume flow rate of scrubbing liquor, $\dot{V}_g$ is the volume flow rate of gas, d_l is droplet diameter, ϱ_l is droplet density, v is maximum gas velocity, μ is gas viscosity, and F a function of the inertial parameter Ψ and an empirical fitting parameter f ($0.25 < f < 0.5$). The following approximation is given for the function F in the range $1 \leq \Psi \leq 4$.

$$F(\psi, f) \approx 0.312 \cdot \psi f^2 \tag{5}$$

Equation (4) can also be used, along with a pressure-drop equation, for optimization. In general, model calculations indicate that higher relative velocities and increased addition of scrubbing liquor lead to better collection efficiency; this is also observed experimentally.

Calculation of the pressure drop is of interest chiefly for venturi scrubbers. Empirical formulas and model calculations are available for this purpose. The empirical Equation (7) is based on the procedure for evaluating flow in pipes.

$$\Delta p = \left(C_1 + C_2 \frac{\dot{V}_l}{\dot{V}_g} 10^3\right) \frac{\varrho_f v 2}{2} \tag{7}$$

C_1 and C_2 are empirical constants, with typical values $0 \leq C_1 \leq 0.5$ and $0 \leq C_2 \leq 1.7$; ϱ_f is gas density.

7.1.5. ***Filters***

7.1.5.1. *General*

Filters constitute an important aid in modern particle collection technology, especially when highly efficient collection in the finest particle-size range is required. Many versions are available. Of all collectors, filters have the widest spectrum of applications and thus a large share of the market.

With regard to application, design, and mode of operation, filters for dust collection can be classified in different but overlapping groups. Three main classes are the so-called deep-bed filters, surface filters, and granular-bed filters.

7.1.5.2. *Deep-Bed Filters*

Deep-bed filters (fibrous filters) are used where dust loads are low, on the order of several milligrams per cubic meter of gas. Typical applications include air conditioning and ventilation, laboratory exhaust systems, clean rooms, and respiratory protection. The filters consist generally of a relatively loose fiber mat with a pore fraction over 90 % (often > 99 %). As the gas flows through the fibrous layer, particle collection takes place in the interior of the layer, where the dust accumulates (deep-bed filtration). After becoming saturated with dust, these filters are usually discarded; some can be cleaned by washing or blowing. Typical gas velocities are 0.1 – 3 m/s.

7.1.5.3. *Surface Filters*

Mode of Operation and Basic Designs. Surface filters (fabric filters) are used for high dust loads, on the order of several grams to hundreds of grams per cubic meter. This is the typical range for industrial dust removal and air-pollution control. The principal surface-filter media are nonwovens and (needled) felts composed of randomly arranged glass, plastic, or ceramic fibers. Woven materials, chiefly constructed from glass-fiber yarns or metal wires, are also employed. Only at the beginning of filtration do these media trap particles in the interior of the fibrous layer. As more dust is deposited, it bridges the fibers and forms a dust layer (filter cake) on the surface.

The fractional efficiency curves in Figure 42 show the improvement in collection performance as more dust is collected and pressure drop increases. The new, clean filter gives a typical depth-filter curve. Since the cake-formation phase lasts only

a short time for the dust loads usually encountered in practice, the interception effect inside the cake is dominant. This process is called surface filtration. Emission levels of <1 mg/m^3 can be achieved.

Figure 42. Variation in fractional collection efficiency due to dust deposition on a polyester needled felt

Amount of dust deposited, g/m^2: a) 4, Δp = 33 Pa; b) 14; c) 29; d) 47; e) 75; f) 95, Δp = 110 Pa

As the amount of dust deposited in and on the filter grows, the pressure drop also increases. After a certain time, or when a predetermined pressure-drop value is reached (ca. 1000 – 2500 Pa), the dust must be removed (cleaned off) to regenerate the filter.

In modern commercial filter media, surface coating or treatment is used with the aim of collection on the surface right from the start and to prevent particles from penetrating into the medium. This approach yields high initial collection efficiencies, avoids the danger of plugging, and facilitates removal of the filter cake.

The three most important surface-filter designs are round bag, envelope, and cartridge. A filter unit contains the requisite number of filter elements connected in parallel. Designs differ primarily in the method of cleaning and sometimes in the way the dirty gas is introduced.

Round bag filters are used most widely. Typical bags are 100 – 300 mm in diameter and 1.5 –10 m long. The classical design is a multichamber filter with shaker cleaning. Dirty gas is fed into the bags from below; it then flows through the filter medium and is led to a clean-gas duct at the top of the device. Particle collection takes place on the inside of the bags. For cleaning, the dirty-gas supply is cut off from one chamber at a time, and the dust is loosened by shaking or rapping the bag support. The dust removed from the bags falls into a dust hopper; purge air drawn into the bags from outside aids this process.

Pulse-jet filters (Fig. 43) became more widely used as progress was made in needle felts. The gas always flows from outside to inside, so the bags must be pulled over supporting frames. For cleaning, a jet of compressed air is admitted to the bag through its open top end. The compressed-air jet suddenly raises the pressure in the bag, which is rapidly inflated and gas flow is reversed. The dust is thus dislodged from the outside of the bag. Because single bags or single rows of bags must be removed from the filtration process for only a short time (ca. 0.1 – 0.3 s), the filter need not be divided into chambers, and cleaning can be done on-line.

Design Calculations. The main purpose of surface-filter design is to determine the required filtration area A, which is given by the ratio of the volume flow rate of dirty gas $\dot{V}$ and the filtration velocity or filter load v. The filtration velocity is selected on the basis of empirical values because of a lack of generally valid models.

The pressure drop Δp is assumed to be the sum of the contributions of the medium and the filter cake. This leads to Equation (8), where K_1 is the residual resistance of the filter medium after cleaning, K_2 is the specific resistance of the filter cake, W is the mass of dust collected per unit filter area, and μ is the gas viscosity. Since W is proportional to filtration time, the second term describes the time dependence of Δp.

$$\Delta p = K_1 \mu v + K_2 \mu W v \tag{8}$$

Important parameters in this equation are the resistances K_1 and K_2; as a rule, they are not constants but functions of several variables. Prediction of these parameters is still problematic because the functions are not sufficiently well known. Even when K_1 and K_2 can be determined experimentally, great care must be taken to ensure that conditions in the experimental device and the full-scale plant are comparable.

Operational Characteristics. Particle collection in a surface filter occurs mainly in the dust layer formed on the surface. Therefore, this highly efficient cake must be retained on the surface as long as possible.

Figure 44 shows that the pressure drop Δp increases as more dust is deposited, and periodic cleaning is necessary. After cleaning, the pressure drop falls to a value that depends on the flow resistance of the filter medium (including residual dust); this value is higher than the initial pressure drop of the new, clean filter. For stable filter operation the residual pressure drop must reach an approximately constant value after an induction period. The filter medium, filtration velocity, and the method and intensity of cleaning determine whether stable filtration is attained for given gas and dust properties.

Figure 44. Pressure drop (A) and dust content (B) in clean gas versus filtration time at constant filtration velocity

The values Δp_1 and Δp_2 denote the pressure-drop contributions of the filtration medium and filter cake, respectively

During and immediately after cleaning, the particle content of the clean gas increases. This occurs partly because the filter cake, which acts as a layer of filter aid, has been removed. Especially with reverse-pulse cleaning, some of the dust passes through the filter medium because after the pressure pulse inside the bag has decayed, the filter medium falls back against the cage and knocks remaining dust through the filter.

7.1.5.4. *Granular-Bed Filters*

In granular-bed filters, the dust-laden gas stream flows through a bed of gravel, sand, ceramics, activated carbon, etc. and is thereby cleaned. The granular-bed functions as a filter medium and can be regarded as a depth or surface filter. Besides pure particle collection, simultaneous removal of gaseous components can be performed in such filters. Granular-bed filters are used chiefly for the removal of hot, chemically aggressive, abrasive, or adhesive dust or when danger of fire exists.

Granular-beds can be either fixed or moving. Filters with fixed beds are operated batchwise; when dust deposition has raised the pressure drop to a predetermined limit, the dirty gas stream is cut off and the bed is regenerated. The dust is removed internally by reverse flushing and agitation or stirring, or externally by screening or other means. In filters with moving beds the granules creep through the filter chamber by gravity, either steadily or at intervals. Fresh granules are added continuously from above. Regeneration takes place in an external loop. This filtration method operates without interruption of the dirty-gas stream.

The design of granular-bed filters is mainly empirical (as in collection generally). Typical initial fractional collection efficiency curves (no dust load in the bed) are shown in Figure 45.

7.1.6. ***Electrical Precipitators***

7.1.6.1. *Mode of Operation and Basic Designs*

An efficient way of separating particles from gases is based on the forces exerted on charged particles in an electric field. This principle is important when inertial forces are no longer effective, i.e., for fine particles with diameters < 1 µm. Because the required capital investment is rather large, the main application of these precipitators is in dust removal from large gas streams (up to several million cubic meters per hour). Emission levels significantly lower than 20 mg/m^3 can be achieved if the dust properties are favorable. Pressure drops are generally slight (< 500 Pa).

The collection principle used in electrical precipitators is depicted in Figure 46 and involves three successive steps: charging of particles, transport of particles to the collecting electrode, and removal of particles gathered on the collecting electrode.

Figure 46. Schematic diagram of charging and collection process

a) High-voltage power supply; b) Emission electrode; c) Electron; d) Neutral molecule; e) Ionized molecule; f) Charged dust particle; g) Collected dust particle; h) Collecting electrode

The ions needed for particle charging are produced by corona discharge at the emission electrodes, which are made of thin wires or tapes with barbs. To obtain optimal collection efficiencies, high field strengths and high corona currents are required. The d.c. voltage is, therefore, adjusted to establish a condition as close as possible to electrical breakdown (ca. 60 – 80 kV), which depends on electrode geometry and gas properties.

Depending on particle size, the attachment of gas ions to particles occurs by one of two mechanisms: field charging or diffusion charging. Field charging dominates in the particle-size range above ca. 1 µm. The ions move toward the collecting electrodes along the electric field lines. As they move, the ions collide with particles and become attached to them. Diffusion charging results from random thermal motion of the ions (Brownian motion) and is important chiefly for particles smaller than 1 µm.

Charged particles are transported to the collecting electrode and must adhere to it. The electrical properties of the particles, particularly resistance, are important for the behavior of both the particle on impact and the resulting dust layer.

The favorable resistivity range for collection is 10^4 – 10^{11} Ωcm. Particles with a lower resistance give up their charge quickly when they collide with the collecting electrode; they change their polarity and are repelled from the electrode back into the gas stream. If the resistance is too high, the particles form a layer that continues to accumulate more charge, thus leading to a weakening of the electric field and discharge effects in the porous dust layer (back corona).

There are two main designs of precipitators. Wire-in tube precipitators are employed for small quantities of gas and especially for the collection of liquids. The wire emission electrodes are stretched along the central axis of parallel tubes. The inside walls of the tubes serve as collecting electrodes. If the tubes are set up vertically, the collected liquid runs down the walls as a film. If solid particles are collected, they are frequently rinsed out by flushing the tubes with water. The tubes are usually 0.2 – 0.3 m in diameter and 2 – 5 m long.

Parallel-plate precipitators contain many plane or profiled plates suspended at uniform intervals (200 – 600 mm) as collecting electrodes (Fig. 47). Gas flows horizontally in the channels between plates. Emission electrodes hang in the midplane between neighboring plates. Particle removal may be either dry or wet. In dry electrostatic precipitators, the dust layer collected on the plates is removed periodically by rapping the plates with hammers, whereby the dust falls into the hopper beneath the plates. The total plate length is divided into several zones for two purposes: dust reentrainment is reduced because the zones can be cleaned at different times; and separate zone-by-zone power controls allow the voltage to be adjusted in accordance with dust concentration.

Figure 47. Schematic of a two-zone parallel-plate electrical precipitator (vertical sections A and B are shown at right-angles to each other)

a) High-voltage power supply; b) Emission electrode; c) Collecting electrode; d) Hopper

In wet electrostatic precipitators, the collecting electrodes are cleaned by flushing with water. The dust flows down off the plates with the water; dust reentrainment is thus effectively prevented.

7.1.6.2. *Design Calculations*

Calculations for precipitator design are concerned with collection efficiency; the very small pressure drop is not important. The well-known Deutsch precipitator equation is still used as the basis for dimensioning precipitators and for evaluating and interpreting measurements. If turbulent flow in the precipitator is assumed and if reentrainment is neglected, the Deutsch equation for fractional efficiency is

$$T(x) = 1 - \exp\left[-\frac{2L}{av}w(x)\right] \tag{9}$$

where L is the collection length, a is the plate spacing (parallel plate precipitators) or the radius of the tube (tube precipitators), v is the gas velocity, and $w(x)$ is the so-called migration velocity. Equation (9) can also be written as

$$T(x) = 1 - \exp\left[-\frac{A}{\dot{V}}w(x)\right] \tag{10}$$

where A is the surface area of the collecting electrodes and $\dot{V}$ is the volume gas flow rate.

The migration velocity $w(x)$ depends on the particle size and charge, the electric field, and the gas viscosity. It can be derived theoretically by solving the equation of particle motion. In practice migration velocity is calculated from the measured fractional efficiencies, by means of Equation (10); it often lies in the range of 10 – 30 cm/s. The parameter $w(x)$ is basically a transport coefficient that characterizes particle transport to the collecting electrode; it is thus vital for dimensioning electrical precipitators.

7.2. Waste-Gas Purification by Thermalor Catalytic Reactions

In thermal and catalytic waste-gas purification processes, gaseous air pollutants are converted by chemical reactions (oxidation, reduction, or decomposition) into harmless substances. These reactions can occur in flames (combustion [542]) or combustion chambers (e.g., thermal oxidation), or over catalysts (e.g., catalytic oxidation). In the following sections these processes are discussed with regard to their possible applications and the process and plant concepts.

7.2.1. ***Fundamentals***

7.2.1.1. *Types of Reaction*

Air pollutants can be disposed of in the gas phase at the site of emission by thermal and catalytic reactions. By utilizing the reaction energy of the exothermic reactions, thermal recycling is possible but not the recycling of material. The latter can be achieved by absorption, adsorption, condensation, or membrane processes.

The disposal effect in the case of thermal and catalytic processes consists in the conversion of the air pollutants into harmless reaction products by chemical reactions. These can be divided into oxidation reactions, reduction reactions, and decomposition reactions.

Substances regarded as harmless here include species natural to the air such as CO_2, H_2O, and N_2. Some examples of

reactions with their characteristic quantities and applications follow:

Oxidation reactions	
Example	catalytic hydrocarbon combustion
	$C_mH_nO_p + (m + n/4 - p/2)\ O_2 \longrightarrow m\ CO_2 + n/2\ H_2O$
Temperature	200 – 600 °C
Residence time	0.42 – 0.02 s
Space velocity	5000 – 50 000 h^{-1}
Application	catalytic afterburning, engine exhaust gas cleaning
Reduction reactions	
Example 1	selective catalytic nitrogen oxide reduction (SCR)
	$4\ NH_3 + 4\ NO + O_2 \longrightarrow 6\ H_2O + 4\ N_2$
Temperature	200 – 400 °C
Residence time	0.2 – 0.3 s
Space velocity	1000 – 5000 h^{-1}
Application	$DeNO_x$
Example 2	nonselective catalytic nitrogen oxide reduction (NSCR)
	$CO + NO \longrightarrow 1/2\ N_2 + CO_2$
	$C_mH_n + 2\ (m + n/4)\ NO \longrightarrow (m + n/4)\ N_2 + n/2\ H_2O + m\ CO_2$
Temperature	200 – 600 °C
Residence time	0.42 – 0.02 s
Space velocity	5000 – 50 000 h^{-1}
Application	engine exhaust gas cleaning
Decomposition reactions	
Example	catalytic ozone decomposition
	$2\ O_3 \longrightarrow 3\ O_2$
Temperature	20 – 100 °C
Residence time	0.7 – 0.3s
Space velocity	5000 – 10 000 h^{-1}
Application	water purification

Thus additional reactants (oxidizing agents, e.g., O_2, and reducing agents, e.g., NH_3) are required for conversion of air pollutants.

On the basis of the oxygen demand in oxidation processes, it is technologically reasonable to classify the gaseous emission streams as waste air streams (high O_2 content, differing little from the natural composition of the air and sufficient for safe burner operation) or waste gases (inert, low O_2 content, burners require additional fresh air for operation). In the following, however, in conformity with the definition of [543], carrier gases with solid, liquid, or gaseous emissions are referred to as waste gases.

7.2.1.2. *Reaction Engineering*

7.2.1.2.1. Homogeneous Gas-Phase Reactions

The course of homogeneous gas-phase reactions can be broken down into three process steps:

1. Preparation (e.g., atomization, swirling)
2. Mixing (diffusion, convection)
3. Reaction of the reactants

High- and low-temperature mechanisms have been formulated for the oxidation of hydrocarbons [544-551]:

1. High-temperature mechanisms: radical-chain mechanism at $T > 1000$ K
   hydrocarbon $\longrightarrow$ intermediate products
   intermediate product $\longrightarrow$ carbon monoxide
   carbon monoxide $\longrightarrow$ carbon dioxide
   (the last step is rate-determining)
2. Low-temperature mechanisms: $T < 1000$ K, formation of partially oxidized intermediate products, such as aldehydes, ketones, alcohols, peroxides, hydroperoxides, and carboxylic acids

The rate of the overall process is determined by the design parameters temperature, time, and turbulence.

The exothermic oxidation and reduction reactions (e.g., combustion) used for waste-gas purification are in practice carried out at temperatures so high that the reaction step is not rate-determining. The main task in carrying out the reaction and designing the equipment is mixing the reactants [552].

Flame Combustion. The course of reaction in flames is characterized [553] by high temperatures (>1200 °C), high radical concentrations, and luminescence phenomena.

Flame combustion is used for waste gases containing pollutants in concentrations near the explosion limit. Combustion takes place in flares after addition of air or oxygen, without energy supply (autothermally) or with a small energy supply [554]. By using staged oxygen supply the combustion can be carried out such that reduction reactions occur [555].

Thermal Reactions. Thermal waste-gas purification (e.g., thermal postcombustion or thermal oxidation) is generally used for waste gases whose pollutant concentration is well below the flammability limit. If the explosion limit can be exceeded as a result of output variations, safety devices must be installed [556]. An auxiliary heater provides the required minimum operating temperature in the combustion chamber [544, 545, 552, 553]. The processes occurring there are influenced both by the reactivity of the pollutants [546-551] and by conditions depending on plant design, such as the combustion chamber geometry [548], nature of the auxiliary heating, and flow and temperature fields in the combustion chamber. The operating temperatures of thermal oxidizer plants for reasonable residence times (0.1 – 2 s) are between 700 and 1200 °C, so heat-resistant materials must be used. The thermal energy of the combustion flue gases can be utilized by heat exchange [557], [558].

7.2.1.2.2. Heterogeneous Gas-Phase Reactions, Catalytic Waste-Gas Purification

Kinetics. In catalytic waste-gas purification pollutant gases and vapors are converted to harmless substances by chemical reaction over a solid inorganic catalyst.

Most industrial catalysts are highly porous materials with a large surface for chemical reaction. Because the reactants are present in a different phase from the catalyst, physical transport processes occurring on the catalyst are also important.

The important individual steps of such heterogeneously catalyzed reactions are shown in Figure 48.

Figure 48. Individual steps of heterogeneous catalysis

a) Transport of the reactants through the gas stream to the boundary layer; b) Diffusion of the reactants through the boundary layer to the catalyst's external surface; c) Diffusion of the reactants through the pores to the catalyst's internal surface; d) Adsorption on the catalyst surface; e) Chemical reaction; f) Desorption of the products from the catalyst surface; g) Diffusion of the products through the pores to the catalyst's external surface; h) Diffusion of the products through the boundary layer; i) Transport of the products in the gas stream

The use of solid catalysts in gas reactions (heterogeneous catalysis) raises the rate of the reaction by condensation of the reactants on the catalyst surface and, as a result, increased collision frequency, and by decreasing the activation energy (see Fig. 49).

Figure 49. Simplified potential energy curves for homogeneous and heterogeneous exothermic reactions

Due to the increased reaction rate the conversion of air pollutants by chemical reaction is achieved at lower temperatures and with smaller reactors (shorter residence time) compared with thermal processes.

Requirements of Waste-Gas Purification Catalysts. The *activity* of a catalyst is its ability to increase the rate of a reaction in question under defined conditions. Activity is therefore not a fundamental property, but a property specific to a reaction and process parameters. The following are regarded as alternative measures of activity:

1. The percentage conversion at a given temperature and contact time and inlet concentration
2. The temperatures and contact times necessary to maintain certain percentage conversions or certain concentrations in the purified gas.

Only those reactions should occur on the catalyst that lead to the required products (*selectivity*). For example, during the catalytic total oxidation of hydrocarbons, partially oxidized intermediate products are converted with higher activity than the hydrocarbon. Intermediate products are therefore not emitted [559]. A catalyst should exhibit *stability towards deactivation,* i.e., its properties must remain unchanged for the longest possible lifetime. When selecting a catalyst, special attention must be paid to potential deactivation. It must be verified that

1. The catalyst is resistant to the substances present (often in traces) in the waste gas
2. The catalyst undergoes no structural changes in the operating temperature range
3. The catalyst is sufficiently resistant to abrasion and fracture by vibrations and stresses occurring in operation

Although the catalyst is not consumed in the chemical reaction, a change of properties during operation under industrial conditions must be expected. This leads to reversible or irreversible decrease in the catalytic activity (deactivation). Chemical and thermal factors can limit the effective life of catalysts.

Catalyst poisoning occurs when the waste gas contains substances that react with the catalyst support or the active component.

These undesirable reactions can lead to changes in chemical composition, reduction of surface area, loss of active components, or masking of active centers (e.g., coking).

The rate and frequency of structural changes (crystal growth, spinel formation, sintering) increase greatly with increasing temperature. These structural changes can lead to reduced internal surface area and decreased degree of dispersion of finely-divided active components.

For industrial catalysts, therefore, upper limits are specified for the temperature of use:

Metal oxide catalysts	
bulk catalysts	500 °C
supported catalysts	700 °C
Noble metal catalysts	
aluminum oxide supported	700 °C
stabilized aluminosilicate supported	1000 °C

Catalyst overheating during periods of intense heat of combustion release due to high pollutant concentrations can be avoided by introducing cold air or reducing the preheating.

Catalyst damage caused by mechanical influences include abrasion and fracture. Abrasion can be caused by vibration of the plant, pressure surges, loosening of the catalyst bed, and solid particles (abrasive dusts); and fracture by thermal stress owing to rapid temperature changes, and mechanical stress due to thermal expansions of the reactor.

Mechanical stress in reactors filled with honeycomb catalysts can be compensated by elastic internal seals.

The risk of catalyst beds being fluidized can be avoided by a vertical inlet flow from above. At the same time, however, the formation of a funnel-like bed surface by too high an inlet flow rate or by a swirling incident flow must be avoided.

The *pressure drop* in catalytic waste gas purification reactors can be influenced by selecting an appropriate geometry and type (e.g., honeycomb) for the catalyst as well as by the height of the catalyst bed.

Typical values of the specific pressure drops, per unit bed height, are 10 kPa/m for bulk catalysts and 1 kPa/m for honeycombs.

Reactor Design. Two methods can be used for reactor design.

Computing based on reaction engineering models [560], which are applicable if

1. The following kinetic data, necessary for determining the reaction rate, are known: activation energy, collision factor, reaction order, and kinetics of mass transfer.
2. There is no influence of interfering components.
3. Flow and temperature conditions are known. Simple reactor models are based on assumptions such as isothermal reactor, adiabatic reactor, or pseudohomogeneous reaction (i.e., no influence of mass-transfer processes).

Experimental simulation (*pilot-plant trials*) is more important in practice since:

1. Mixtures of pollutants are present, often with variable concentrations
2. Conditions of flow and temperature vary greatly
3. No kinetic data are available
4. The influence of further crude gas constituents is unknown
5. A pilot-plant trial is often necessary for detecting the presence of catalyst poisons

The results of these experiments are plotted in diagrams showing, for specific pollutants on specific catalysts, the dependence of the percentage conversion on inlet temperature, space velocity (under standard conditions), and inlet concentrations (Fig. 50).

Figure 50. Curves of percentage conversion [559]

Activity comparison of various metal oxide catalysts (pollutant: 1000 ppm ethyl acetate) in air; catalyst aged for 168 h at 500 °C; space velocity = 15 000 h^{-1})

These diagrams can be used as the basis for design according to the following scheme:

1. Determination of the percentage conversion required
2. Determination of the catalyst inlet temperature at the expected inlet concentration (taking into account the temperature rise due to the heat of reaction)
3. Determination of the permissible space velocity under normalized design conditions (SVN)
4. Calculation of the catalyst volume required

$$V_c = \frac{\Phi v, n}{\mathrm{SVN}} = \frac{\text{volumetric flow rate(STP)}}{\text{space velocity(STP)}}$$

If mixtures of contaminants are present, the temperature and space velocity should be determined from the reaction behavior of the least reactive component.

During the catalytic afterburning of hydrocarbon mixtures the individual components are selectively oxidized, so the proportion of less reactive components increases with increasing temperature. The overall fractional conversions therefore exceed the value for the less reactive component.

When designing the catalytic waste-gas purification reactors, it must be ensured that the thoroughly mixed reactants are distributed homogeneously over the entire inlet flow cross section of the catalyst bed. This can be achieved by mixing blades, baffle plates, and straightening blades.

7.2.1.3. *Process Selection and Plant Concepts*

The process is selected primarily from knowledge of the appropriate type of reaction for pollutant conversion under the prevailing waste-gas conditions of temperature, pressure, composition (components and concentration) and required conversion.

The choice of process is also determined by economic considerations [563] such as investment costs; operating costs (energy supply, waste-heat utilization [557], [564], pressure drop); and the life of components such as catalysts, heat exchangers, and valves; formation of byproducts (e.g., HCl during the oxidation of chlorinated hydrocarbons), waste disposal (e.g., of catalysts).

The following process steps can be regarded as the basic operations of waste-gas purification processes:

1. Transfer of the waste gas (e.g., by suction)
2. Mechanical transport of the exhaust air (e.g., by ventilators, compressors)
3. Separation of interfering components (e.g., by filters, adsorbers, absorbers)
4. Heating of the waste gas by heat exchange
5. Supply of external energy (e.g., by burners, electrical resistance heating)
6. Mixing with oxidizing or reducing agents (e.g., oxygen, air, ammonia)
7. Pollutant conversion (e.g., by flame, thermal, or catalytic reaction)
8. Waste heat utilization (e.g., for heating steam or heat-transfer oil)
9. Separation of reaction products (e.g., HCl)
10. Discharge of purified gases (e.g., from the stack)

Economically, integration of waste-gas purification into the production process should be aimed for. In oxidation processes this can be achieved by waste-heat utilization [557], [560], [564], [576].

7.2.1.4. *Operational Check [566], [567]*

Waste-gas purification plants lead to reduced emission mass flow rates.

If waste gas mass flow rates are known, concentration measurements give information on the efficiency of the plant and are prescribed as emission values in permits.

In measuring emission concentrations, it must be taken into account for processes with pollutant conversion that the type of substance can change. Therefore, with thermal combustion processes, for example, the measurement of CO content in the purified gas is specified. Catalytic processes usually operate selectively.

The frequency of emission monitoring is prescribed for the specific plant and adapted to plant size and fluctuations in operating conditions.

For chemical conversions the reaction temperature largely determines the rate of the process. Temperatures (combustion chamber outlet, catalyst inlet/outlet) are therefore frequently used as control variables.

It is not useful to specify standard oxygen contents for oxidative waste-gas purification processes, since the oxygen concentration of the waste gas is predetermined by the emitting process and reduced as little as possible by an energy optimized conduct of the process (i.e. one with reduced fuel requirement) [552].

7.2.2. ***Thermal Processes for Waste-Gas Purification***

7.2.2.1. *Oxidation Processes*

Thermal oxidation processes associated with flames are known as combustion. Complete combustion converts the carbon bound in the atmospheric pollutant or in auxiliary fuels to carbon dioxide. In the treatment of exhaust air streams containing

sulfur or halogens, the formation of SO_2 and HCl or Cl_2 necessitates downstream separation. If chlorine-containing compounds are present, attention must be paid to the formation of polychlorinated compounds. In the presence of precursor compounds (e.g., chlorobenzene), polychlorinated dibenzodioxins and dibenzofurans can be formed under conditions such as local oxygen deficiency, low temperatures (300 – 600 °C), or inadequate residence time in the presence of oxygen.

Therefore in the design of combustion systems (intensive mixing) and waste-heat recovery (rapid cooling), these conditions must be avoided in order to avoid “de novo” synthesis from hydrocarbon radicals and organic or inorganic chlorine [552], [568], [569]. If organic nitrogen compounds or NH_3 are present, nitrogen oxides are formed [546], [549]. These can be avoided by control of the combustion or converted by waste gas aftertreatment.

The sequence of the following process descriptions follows the specific CO_2 formation to be expected, taking into account pollutant conversion, external energy supply, and waste-heat utilization. The amount of CO_2 formed is least if the combustible substances in the waste gas are used as replacement fuel in existing furnaces or stationary motors. With these processes, however, attention must be paid to nitrogen oxide formation. In separate waste-gas purification units, specific CO_2 formation decreases with increasing waste-gas preheating or with increased cooling of the purified gas by waste-heat utilization before discharge to the atmosphere.

7.2.2.1.1. Waste-Gas Disposal in Furnaces [557], [564]

Waste gases containing oxygen can be added to the combustion air of furnaces provided it is ensured, if necessary, by fitting (see Fig. 51), that

1. Deposits from the waste gas (e.g., cracking products) in the air supply system of the burner are avoided
2. The resulting waste-gas stream is always supplied to the heater
3. Fresh air is available for the generation of steam

Figure 51. Waste gas thermal purification in a boiler furnace [557], [564]

a) Collection chamber; b) Steam boiler

Conditions (2) and (3) can be realized by using a vacuum-controlled waste-gas collecting chamber with a fresh-air valve [557].

With regard to condition (2) it must be checked whether there is simultaneity of waste gas production and furnace operation in the correct order of magnitude (approximately 800 – 1000 m^3/h waste gas for 1 t/h steam) [564].

7.2.2.1.2. Thermal Combustion

Waste-Gas Preheating by Regenerative Heat Exchangers [558, 570, 571]. Regenerative heat exchangers are characterized by:

1. The presence of a heat-storage material
2. Position- and time-dependent temperature profiles in the storage material for fixed beds (see Fig. 52)
3. An alternating flow direction (fixed bed) or moving storage materials (moving bed)
   Advantages of these systems are:
4. High degrees of heat exchange

$$n = \Phi_E/\Phi_E\max = \frac{T_{\text{hot,inlet}} - T_{\text{hot,outlet}}}{T_{\text{hot,inlet}} - T_{\text{cold,inlet}}} > 90\ \%$$

5. Homogenization of the flow

Figure 52. Difference between recuperators and regenerators [558]

The following features of this system must be taken into account:

1. Periodically changing mixture of waste gas and purified gas, since the waste gas path is the same as the purified gas path. Therefore, at high preheating temperatures the use of uneven-numbered tower layouts for carrying out a

purging phase with recycle of the unpurified gas is advisable. By opening and closing the respective valves, the tower in purge mode is connected to a line leading to the suction side of the blower. After purging the crude gas from the void fraction of the bed, the hot purified gas from the burner chamber is connected to the purged tower. The bed is heated by heat transfer from the hot gases. Thus the cycle of modes is completed without giving untreated gas access to the purified gas duct.
2. Large weight.
3. Mechanical stress on the moving parts (valves, rotors, seals) with cycle times of 30 – 200 s [558].
4. Fouling of the storage material by waste gas constituents [571].

The same applies to catalytic oxidation with heat exchanger designs of this type [589].

Figure 53 shows a regenerative thermal oxidation plant [572]. The process consists of the following steps:

1. The process exhaust stream enters the oxidizer through the common inlet manifold and passes into a regenerative chamber through a butterfly valve.
2. The exhaust stream then passes through a bed of ceramic heat-exchange matrix, which raises it to near oxidation temperature.
3. The contaminated air then enters the combustion (oxidation) chamber, which is maintained at ca. 800 °C by burners. The heat released by oxidation of the VOCs lowers the fuel consumption of the burners required to maintain the oxidation temperature.
4. The air stream then exits the oxidation chamber through another bed of ceramic heat-exchange matrix. The clean exhaust then gives up 95 % of its thermal energy to the matrix to be reused for preheating on the next inlet cycle.
5. The clean air is then drawn through an outlet valve and exhaust manifold for discharge to the atmosphere.

Figure 53. Regenerative thermal oxidation plant [572]

1) Exhaust inlet; 2, 4) Ceramic heat-exchange matrix; 3) Oxidation chamber; 5) Exhaust manifold

Figure 54 shows various designs of regenerative combustion systems.

Figure 54. Schemes of various regenerative combustion systems [558]

A) Fixed-bed regenerator; B) Combu-Changer; C) Ljungstrom regenerator; D) Moving-bed regenerator

The Combu-Changer and moving bed systems carry out the thermal oxidation in the bed of heat-storage material.

In the other systems, the combustion chamber and heat exchanger are separate [572]. The dimensions are based on a given residence time in the combustion chamber (e.g., 0.5 s) [571]. Since the reactions also occur in the heat bed, the residence time in the total reaction volume is ca. 1 s [567]. Processes that mainly involve thermal oxidation without the action of a flame are known as regenerative thermal afterburning or regenerative thermal oxidation (RTO, thermo-reactor, etc.). At high concentration peaks, thermal energy must be withdrawn from the reaction zone by a bypass to avoid buildup of the temperature [558], [571]. Due to the relatively high combustion space temperature, the large excess of air, and small influence of flame, only small amounts of CO and NO_x are formed.

Typical process parameters and range of application [555]:

Temperature range	800 – 1000 °C
Residence time	ca. 1 s
Conversion	>99.5 %
Heat utilization, waste-gas preheating	90 – 97 %
Waste-gas volume flow rates (STP)	5000 – 10 000 m^3/h
Pollutant concentrations	≤10 % of lower explosion limit
Suitable for continuous waste-gas emission	
Unsuitable for discontinuous waste-gas emission	

Waste-Gas Preheating by Recuperative Heat Exchangers. In these processes the combustion system consists of a burner and an afterburner chamber.

Burner designs are:

1. Flat burner (see Fig. 55)
2. Swirl combustion chamber (see Fig. 56)
3. Lance burner (see Fig. 57)

Figure 55. Flat burner [552]

a) Feeding and monitoring elements; b) Mixing cone; c) Mixing and reaction space

Figure 56. Swirl combustion chamber [552]

a) Swirl flap; b) Annular gap; c) Swirling flow; d) Combustion space; e) Swirling flame

Figure 57. Lance burner [555]

In the burner the auxiliary fuel (preferably natural gas) is burnt. The necessary oxygen can be provided by oxygen-containing waste gases (diffusion burner, types 1 – 3) or, if the oxygen content of the waste gas is insufficient, from combustion air fed to the burner together with the fuel (premixing burner, type 3). The added combustion air increases the waste gas mass flow rate, resulting in increased extraneous energy requirement [557]. Initial pollutant conversion occurs during the mixing of the waste gases with the hot flue gases of the burner, partly by contact with the flame.

The afterburner chamber provides additional residence time at high temperatures for the oxidation reactions to proceed to completion, ensuring total combustion. In the swirl combustion chamber system, burner and afterburner chamber are combined in a single unit. The adjustability of the combustion system must ensure matching to different waste-gas mass flow rates.

For waste-gas preheating the following recuperative gas – gas heat exchangers are used (see Figs. 52, 58):

1. Circular-disk recuperator
   advantage: = space-saving construction, low weight; suitable for compact units
   disadvantage: = sensitivity to fouling, and thermal stress as a result of hindered differential expansions

2. Duct recuperator
   advantage: = robust construction, easily maintained, good compensation of thermal expansions
   disadvantage: = high weight

Figure 58. Recuperator designs [557]

A) Duct recuperator; B) Circular disk recuperator

Units can be classified on the basis of the structural arrangement of these components as compact units (see Fig. 59), which are often integrated into production plants [563], and units with separate arrangement of the components (see Fig. 59).

Figure 59. Compact thermal afterburning units [557]

For units that are started up and shut down frequently, an all-steel construction with ceramic-fiber lining is preferable.

Waste-heat utilization can be carried out by downstream, steam generation, heat-transfer medium heating, or hot-air generation.

Typical process parameters and range of application [555]:

Temperature range	800 – 1200 °C
Residence time	0.3 – 2 s
Conversion	>99.5 %
Heat utilization,	
waste-gas preheating	50 – 55 %
waste-heat utilization	50 – 80 %
Pollutant concentration, % of LEL	
with safety engineering	0 – 100 %
without safety engineering	0 – 50 %
Volume flow rate (STP)	1000 – 50 000 m^3/h
Suitable for continuous waste-gas emission	
Less suitable for discontinuous waste-gas emission	

7.2.2.1.3. Combustion in Flares

Combustion in flares is used mainly in the chemical industry and in plants for oil and natural gas recovery and treatment (e.g. refineries), for waste gases originating from the following operating conditions of the associated production plants [554]:

1. Start-up and shut down
2. Disturbances with controllable operating conditions (e.g., safety valves)
3. Disturbances with uncontrollable operating conditions (e.g., power cut or cooling-water failure)

The construction of a high flare is shown in Fig. 60. The combustion processes occur in the flare stack tips which can be of three types (see Fig. 61) free flame flares, screen flares, and muffle flares.

Figure 60. High flare system [554]

Figure 61. Types of flare [555]

A) Free-flame flare; B) Screen flare; C) Muffle flare

a) Pilot burner; b) Ignition burner; c) Thermoelement

There is no utilization of heat from flares.

Typical process parameters and range of application [555]:

Temperature range	> 800 °C
Residence time	1 – 2 s
Conversion	> 99.5 %
Heat utilization	not provided
Pollutant concentration, % of LEL	
with safety engineering	0 – 100 %
without safety engineering	0 – 50 %
Volume flow rate	≤ 1000 m^3/h

7.2.2.1.4. Safety Engineering in Thermal Waste-Gas Purification

The combustion chamber of waste-gas thermal purification plants constitutes a permanent ignition source. If the waste-gas

composition can be explosive permanently (Zone 0), occasionally (Zone 1), or rarely (Zone 2), then three, two, or one independent protective measures, respectively, must be provided for introduction of the waste gas [556], [573]: (1) low-flashback inlet to burner, (2) explosion safeguard, (3) immersion safeguard.

7.2.2.2. *Reduction Processes*

7.2.2.2.1. Staged Combustion

Waste gases that contain organic nitrogen compounds or NO_x can be purified by combustion with staged oxygen supply. The nitrogen bound in the pollutants is emitted in molecular form (N_2). In the first step an atmosphere with reducing compounds (e.g., CO, H_2, NH_3) is generated by substoichiometric combustion of a fuel (oxygen deficiency). NO_x formation therefore stops, or that which is already present is reduced. This effect can be intensified by cooling (steam addition) in the first step [555]. The unreacted combustibles emerging from this step are afterburnt in the second step with an excess of air ($\lambda > 2$).

For establishing substoichiometric conditions in oxygen-containing waste gases, these processes sometimes require considerable amounts of fuel, with which an energy release is associated. This is a stoichiometric requirement of the process and cannot be decreased by preheating the waste gas [555].

7.2.2.2.2. Thermal Reduction of Nitrogen Oxides

The reactions:

$$4\,NH_3 + 4\,NO + O_2 \rightarrow 6\,H_2O + 4\,N_2$$

$$CO(NH_2)_2 + 2NO + \frac{1}{2}O_2 \rightarrow 2\,N_2 + CO_2 + 2\,H_2O$$

occur as homogeneous gas-phase reductions in a temperature range 900 – 1000 °C. This temperature range can be established in furnace and waste-gas purification plants. Ammonia [555] or urea solution [574] is injected into this temperature zone by lances. By injecting additional chemicals, the temperature range of the urea process has been extended to 500 – 1200 °C, allowing NO_x conversions of > 80 % to be attained [574].

7.2.3. ***Catalytic Waste-Gas Purification Processes***

7.2.3.1. *Catalytic Reduction of Nitrogen Oxides in Flue Gases and Process Off-Gases*

Catalytic reduction is used for the removal of nitrogen oxides from flue gases and process off-gases (e.g., furnaces, nitric acid plant, glass melting, refuse incineration plants). The process is known as $DeNO_x$ or SCR (selective catalytic reduction).

In the SCR process, ammonia is added as a selective reducing agent (i.e., one that is effective even in presence of oxygen), and the nitrogen oxides are converted to molecular nitrogen:

$$4\,NH_3 + 4NO + O_2 \rightarrow 6\,H_2O + 4\,N_2$$

Process description: SCR for power station flue gases

Two process variants can be distinguished. In the *crude-gas circuit* (see Fig. 62).

Figure 62. $DeNO_x$: crude-gas circuit [560]

a) Steam generator; b) Air preheater; c) Filter; d) Induced-draught blower; e) Gas heater; f) Blower; g) Washer; h) Stack

The flue gases are taken off directly from the steam generator (after the boiler feedwater preheater, before the combustion air preheater) and, after addition of the reducing agent, passed over the catalyst.

The flue gas, now largely free of nitrogen oxides is introduced into the combustion air preheater to preheat the combustion air (heat recovery). Other off-gas purification stages (dedusting, desulfurization) follow.

Crude-gas preheating or addition of fuel prior to the catalyst is not necessary since the flue gas is removed from a point in the steam generator where it is sufficiently hot (350 – 450 °C).

The catalysts are either bulk honeycombs in the fixed-bed process (Ti, V, Fe, W, Ni, Co, Cu, Cr, U, Mo, Sn as oxides, Ag, Be, Mg, Zn, Al as metals); these can also be used for removing dioxins from flue gases in municipal waste incineration plants [575], or activated coke in the moving bed process [576].

Catalyst requirements are selectivity ($SO_2 \longrightarrow SO_3$ conversion must be avoided), activity (low NH_3 consumption), and high abrasion resistance owing to the dust content of the flue gases.

In the *clean-gas circuit* (see Fig. 63), dust and sulfur oxides are removed by electric precipitators or flue-gas scrubbers before the crude gas/reducing agent mixture reaches the catalyst. The crude gas must be preheated to the required

reaction temperature of 300 – 400 °C.

Figure 63. $DeNO_x$: pure-gas circuit [560]

a) Steam generator; b) Air preheater; c) Filter; d) Gas heater; e) Blower; f) Gas heater; g) Washer; h) Stack

Honeycomb catalysts are used, similar to those of the crude-gas process, but with higher activity. Prior separation of interfering components means that demands on the selectivity are lower and a longer effective life can be expected.

Typical design parameters

Space velocity	1000 – 10 000 h^{-1}
Temperature	250 – 450 °C
NH_3 addition ratio	
of the stoichiometric ratio	≤ 100 %

7.2.3.2. *Engine Exhaust Emission Control*

Exhaust emissions from internal combustion engines contain pollutants of the following three classes: hydrocarbons (C_mH_n), carbon monoxide (CO), and nitrogen oxides (NO, NO_2).

By using special catalysts and a suitable air-to-fuel ratio in spark-ignited internal combustion engines the three classes of pollutants can be removed together in a single catalytic converter.

The main reactions, occurring in parallel, are [577]:

1. Oxidation reactions

$$C_mH_n + (m + n/4)O_2 \rightarrow mCO_2 + n/2\,H_2O$$

$$CO + 1/2\,O_2 \rightarrow CO_2$$

$$H_2 + 1/2\,O_2 \rightarrow H_2O$$

2. NO-reducing reactions (nonselective catalytic reduction)

$$CO + NO \rightarrow 1/2\,N_2 + CO_2$$

$$C_mH_n + 2(m + n/4)NO \rightarrow (m + n/4)N_2 + n/2\,H_2O + mCO_2$$

$$H_2 + NO \rightarrow 1/2\,N_2 + H_2O$$

The catalyst is integrated into the exhaust system of the engine.

Owing to the predetermined exhaust gas temperature, preheating or external energy supply is unnecessary. The required concentrations of oxidizing agents (O_2, NO) and reducing agents (C_nH_m, CO, H_2) are established by feedback to the air-to-fuel ratio in the engine [578] using an electronic lambda probe. In the case of block power stations driven by gas engines, the thermal energy of the purified gases is recovered. Noble-metal-coated honeycomb catalysts are used. The noble metals are mainly platinum, palladium, and rhodium. Coating and support are optimized for high thermal stability.

Typical design parameters

Start-up temperature	ca. 200 °C
Space velocity	up to ca. 10^5 h^{-1}
Pressure drop	<1 kPa

Exhaust emissions from diesel engines can lead to problems in industrial safety and environmental protection owing to their content of hydrocarbons and derivatives e.g., aldehydes) (HC), carbon monoxide (CO), nitrogen oxides (NO, NO_2), and particles (soot, polycyclic aromatics).

Oxidizable constituents (hydrocarbons, CO) can be removed from the exhaust gas by oxidation catalysts.

High catalyst selectivity is required since the oxidation of SO_2 to SO_3 and of NO to NO_2 must be avoided [579]. For retaining the particles various mechanical and electrostatic systems are known. The honeycomb filter has a catalytic coating and can be regenerated by burning off at ca. 400 °C.

Owing to the high oxygen content of diesel exhaust, the three-way catalysts cannot be used to decrease the NO_x content. The NO_x can be decreased by primary measures (e.g., exhaust gas recycling and filtration) or selective secondary measures (SCR: see Section Catalytic Reduction of Nitrogen Oxides in Flue Gases and Process Off-Gases).

7.2.3.3. *Gas-Turbine Exhaust Emission Control*

SCR catalysts are available for gas turbine cogeneration and combined cycle installation [580]. A newly developed zeolite catalyst is available for the simple cycle gas turbine applications which require higher catalyst operating temperatures. A typical gas turbine SCR system is outlined schematically in Figure 64.

Figure 64. Typical cogeneration heat recovery steam generator (HRSG) installation [580]

7.2.3.4. *Catalytic Purification of Claus Plant Off-Gases*

Sulfreen Process [581], [582]. Typical Claus plant off-gases contain 1 % H_2S and 0.5 % SO_2.

In the Sulfreen process (Fig. 65) the reactions of the Claus process occur at fairly low temperatures (120 – 140 °C). Beds of modified alumina catalyst are used. The elemental sulfur formed by reaction of H_2S with SO_2 is adsorbed in the pores of the aluminum oxide, reversibly poisoning the catalyst. Cyclic purging with hot inert gas is used to regenerate the catalyst and recover sulfur.

Figure 65. Sulfreen process [560]

a) Adsorption, reaction; b) Desorption; c) Afterburning; d) Condensation

Catalytic Afterburning [583]. Sulfur compounds (H_2S, COS, CS_2) remaining in the waste-gas stream must be oxidized to SO_2 before the gas is discharged to the atmosphere. At high waste-gas volume flow rates the energy consumption is distinctly reduced, compared with thermal combustion methods, by using alumina-containing catalysts.

7.2.3.5. *Catalytic Oxidation in Industrial Off-Gas Streams*

Total Oxidation. Industrial and commercial exhaust air streams that contain oxidizable impurities can be purified by catalytic total oxidation (catalytic afterburning) [579], [584-587]. Table 19 shows some examples of the reactions. The use of catalytic afterburning is restricted by the presence of catalyst poisons and by the need to prevent catalyst overheating with highly variable pollutant loadings.

Table 19. Combustion reactions and heating values of some air pollutants [575]

Compound	Combustion reaction	Heating value, kJ/kg	ΔT_{ad}, K, in air per 1 g/m^3
Toluene	$C_7H_8 + 9\ O_2 \longrightarrow 7\ CO_2 + 4\ H_2O$	40 935	30.6
Methanol	$CH_3OH + 1.5\ O_2 \longrightarrow CO_2 + 2\ H_2O$	21 119	15.8
Acetone	$C_3H_6O + 4\ O_2 \longrightarrow 3\ CO_2 + 3\ H_2O$	29 065	21.9
Ethyl acetate	$C_4H_8O_2 + 5\ O_2 \longrightarrow 4\ CO_2 + 4\ H_2O$	23 530	18
Carbon monoxide	$CO + 0.5\ O_2 \longrightarrow CO_2$	10 423	7.5
Ammonia	$NH_3 + 0.75\ O_2 \longrightarrow N + 1.5\ H_2O$	18 424	13.9
Hydrogen sulfide	$H_2S + 1.5\ O_2 \longrightarrow SO_2 + H_2O$	15 355	11

Noble metal and metal oxide catalysts can be used for total oxidation [586].

Example 1: catalytic afterburning unit with recuperative waste-gas preheating [588].

Styrene-containing exhaust air is emitted from a plant for producing glass fiber reinforced plastic moldings. After reducing the exhaust-air volume flow rate by enclosing the production machines, the catalytic afterburning unit was designed for a volumetric flow rate (STP) of 15 000 m^3/h with a styrene loading (STP) of ca. 5 g/m^3. The heat exchanger allows the unit to operate autothermally above a loading (STP) of ca. 2.5 g/m^3. At higher loadings, heat recovery for heat-transfer fluid heating is possible.

Operating data:

Temperature	
Crude gas	30 °C
Catalyst inlet	320 °C
Catalyst outlet	470 °C
Stack	100 °C
Heat recovery (heat-transfer oil heater)	465 kW
Average natural gas consumption (for heating at low pollutant concentration)	6 m^3/h
Electrical load connected	50 kW
Catalyst volume	800 L
Catalyst type	honeycomb EnviCat KCO WK 4100 with 1 g Pt/L

The concentrations in the purified gas are less than 10 mg/m^3, and odor nuisance in the surroundings of the plant is hence avoided [560].

Example 2: regenerative catalytic oxidation (RCO [561]) with waste-gas preheating (Fig. 66).

1. The VOC-laden process exhaust stream enters the oxidizer through an inlet manifold and is allowed to enter a regenerative chamber by means of control valves.
2. The airstream passes upwards through a bed of hot ceramic heat-sink material [562] and is heated to a temperature which allows oxidation to occur in the presence of catalyst.
3. The VOCs passing through the upper catalyst layer are oxidized.
4. The combustion chamber is used to regulate the temperature of the airstream so that, in conjunction with thermal transfer to the heat sink and catalyst oxidation, the airstream is regulated to the correct temperature for complete oxidation to occur.
5. The airstream passes downwards through an exit layer of catalyst [561] to complete the oxidation process.
6. As the hot oxidized airstream passes downwards through the next regenerative chamber, the heat is absorbed by the cooler bed of ceramic heat-sink material. After the heat sink in the inlet chamber has been heated and cooled, and the heat sink in the outlet chamber heated, the airflow control valves are reversed, so that the chambers operate alternately as inlet or outlet chambers.
7. The cleaned airstream is drawn through the outlet manifold and discharged to atmosphere by an induced-draft blower.
8. The transition duct is used to provide smooth pressure conditions while the flow direction is being reversed.

Figure 66. Catalytic oxidation with waste-gas preheating [561]

1) Exhaust inlet; 2) Bed of ceramic heat-sink material; 3) Catalyst layer; 4) Combustion chamber; 5) Exit layer of catalyst; 6) Regenerative chamber; 7) Outlet manifold; 8) Transition duct

Combination of Thermal and Catalytic Afterburning [560]. To the operator of thermal afterburning units it often seems desirable to reduce the combustion chamber temperatures, to reduce energy consumption (natural gas) and the fatigue or wear of components such as burners or exhaust air heat exchangers.

However, this also leads to formation of intermediate products of hydrocarbon oxidation. Relatively high combustion chamber temperatures (>750 °C) are necessary to ensure that the aldehydes and carbon monoxide formed as

intermediate products in the combustion chamber are converted to carbon dioxide within the predetermined residence time.

If conditions of flow, temperature, or residence time are unfavorable (e.g., during capacity changes), the emission of secondary pollutants (e.g., CO) can be detected in the flue gas of thermal afterburning units.

Increasing the combustion chamber temperature is a suitable countermeasure, but this often runs up against equipment limitations. Moreover, it must be investigated how far the temperature can be raised without significantly increasing the NO_x emissions.

The use of waste-gas purification catalysts enables secondary pollutant emission to be avoided. A lower combustion chamber temperature that ensures oxidation of the primary pollutants (solvents) with reliable observance of the emission limits can then be used.

The object of combining homogeneous and heterogeneous pollutant combustion (thermal and catalytic afterburning) is the conversion of hydrocarbons in the gas phase, and of carbon monoxide and unburnt hydrocarbons on the catalyst.

By dividing the reaction stream into two reaction zones as well as by matching the operating temperature to the thermal ignition temperature of the hydrocarbons, the catalyst can be designed for a higher space velocity than in the case of a single-stage catalytic combustion unit. As a result of the lower concentrations at the entrance to the catalyst stage, smaller temperature differences between inflow and outflow are to be expected.

Owing to the relatively high inlet temperatures for waste-gas purification catalysts, a high thermal stability is demanded of the catalyst. In addition, particularly when refitting old plants, only a relatively small pressure drop is available for flow through the catalyst stage. Therefore, honeycomb catalysts with a large surface area for incident flow are preferred.

For example, in an adhesive tape processing plant a thermal afterburning unit has been retrofitted with a catalyst stage, which allows the exhaust air flow of 30 000 m^3/h (STP) and contaminated with ca. 10 g/m^3 solvent, to be purified at a combustion chamber temperature of ca. 500 °C [560]. The installed catalyst volume is 1 m^3. For hydrocarbons and CO the concentrations measured in the purified gas at the stack are distinctly below the emission limits.

Droplets of high-boiling hydrocarbon compounds (aerosols), which are present in the waste gas and on contact with the catalyst surface could lead to coking or the masking of active centers, are vaporized in the combustion chamber. These compounds therefore burn in the vapor state without residue.

Rotary Concentrator Adsorption (RCA) System (Fig. 67) [562]. An RCA system increases the fuel value of VOC-laden gas streams and the fuel economy of the oxidizer by raising the VOC concentration in the inlet gases. The RCA uses a rotating adsorption bed of zeolite or activated carbon to trap VOCs and vents the cleaned air to the atmosphere. As the bed revolves, the trapped VOCs are subjected to a warm stream of desorption air and are released. This much-reduced volume passes into the oxidizer for final treatment. Savings vary, depending on the nature of the emission flow and operating conditions. A concentrator will affect the selection of the oxidizer type, and the combination of concentrator and oxidizer must be evaluated as an integrated system.

Figure 67. Rotary concentrator adsorption system [562]

7.3. Absorption

7.3.1. *Introduction*

Absorption is a process for removing some components of a gas stream by contact with a liquid phase (solvent). The desired selectivity with respect to the component(s) to be removed (solute) depends either on purely physical interactions (physical absorption) or on strong chemical bonding (chemical scrubbing or stripping). So-called physicochemical scrubbing occupies an intermediate position. Here, dissolution takes place in the absorbing liquid due to physical interaction accompanied by a reversible chemical reaction.

There are three major industrial applications of absorption processes. In one large group applications, undesired components such as H_2S or organic sulfur compounds, and, in some cases, water vapor, are removed from natural gas, refinery gases, synthesis gases, or process gases. Another major application is the removal of gaseous pollutants such as hydrogen halides or volatile organic solvents from waste air. The third group includes the removal of SO_2 and NO_x from the flue gases of power stations or domestic waste incinerators.

This section treats the industrial use of equipment for absorption processes. The discussion is limited to processes in which only absorption takes place. Apparatus principally intended for wet scrubbing of solids and only incidentally performing an additional absorption function, such as venturi or rotary scrubbers, is described in Section Separation of Solid and Liquid Particles from Gases .

7.3.2. *Basic Principles of Absorption Processes*

The most important element of an absorption plant is the absorber (Fig. 68), in which the gas stream being treated and the

solvent are brought into contact. The purified gas and the loaded solvent then leave the absorber. In some cases (e.g., absorption of HCl and NO_x with water; absorption of NH_3 with sulfuric acid) the loaded solvent is itself a usable product, so that a solvent regeneration stage is not required.

Figure 68. Flowsheet of an absorption process

a) Absorber; b) Desorber; c) Cooler; d) Recuperator; e) Boiler

However, in most cases it is necessary to regenerate the solvent for closed-loop recycling to the absorption stage. This takes place in the desorption stage, which can be a distillation step, as shown in Figure 68. Alternatively, steam or inert-gas stripping is sometimes used. For thermodynamic reasons, desorption should be operated at high temperature and low pressure. The efficiency of the recuperator (d) is thus important for the economics of the process. In physicochemical scrubbing, a desorption process can be considered if the chemical bonding can be broken by pressure reduction or temperature increase, but if the chemical bond is very strong the solvent cannot be regenerated. In most cases where this happens, the charged absorbing liquid is itself a usable product.

The absorption and desorption stages can be designed according to established methods (see ⟶ Distillation and Rectification) based on knowledge of the equilibrium between the partial pressure of the gaseous component in the gas phase and its concentration in the liquid phase. Details of these solution equilibria can be found in the comprehensive reference books [589], [591]. For newer processes, such as the absorption of organic substances in high-boiling solvents, special literature should be consulted [592].

The operating costs of a combined absorption/desorption plant mainly depend on the recirculating flow of solvent. As heat recovery in the recuperator is incomplete, the recycled solvent must be further cooled. To maintain thermal balance, it is therefore necessary to supply energy to the desorption stage. This occurs at the bottom of the desorption column if distillative treatment is used, or by a superheater before the inlet to the desorption column in the case of stripping. Note that desorption (with the exception of inert gas stripping) requires a certain minimum supply of steam, depending on the substance being desorbed, and this requires additional energy input to the process.

The heat of absorption is liberated in the absorption process; it is usually slightly higher than the enthalpy of condensation of the absorbed gas. However, in the case of strongly nonideal equilibria, the heat of absorption may be very high (e.g., 2100 kJ/kg for HCl). This fact, together with the possibility of heat and mass transfer between the gas and liquid streams due to different inlet conditions, must be taken account of in the design, especially of the absorption stage.

7.3.3. *Operating Principles of Absorption Apparatus*

The thermodynamic design of an absorption apparatus usually leads to a requirement for a certain number of theoretical plates needed to produce the required quality of the purified gas. This can only be achieved by use of the countercurrent principle, whereby the two process streams pass through the apparatus in opposite directions. However, in this context it is immaterial whether the flow in the individual stages is countercurrent or cocurrent (see Fig. 69). The concentration change represented in the distribution diagram shows that the same degree of separation can be produced in both cases with the same number of theoretical stages. The essential difference is that in cocurrent flow, one stream (5) in a unit flows in the opposite direction to the principal flow direction. Therefore individual stages always represent separate units of apparatus. With countercurrent flow, the required number of theoretical stages can be achieved in a single column. In special cases, a semicontinuous mode of operation is used in which an absorption process takes place in each stage, and after a certain period of time the solvent is pumped in countercurrent flow to the next stage, with fresh solvent being added to the first stage.

Figure 69. Internal flow in multistage co- and countercurrent processes

Representation of concentrations in McCabe – Thiele diagrams

The removal of large amounts of heat of absorption requires modifications of the apparatus (Fig. 70). In design (A) the heat removal takes place in the apparatus. Good results have been obtained using film absorbers or tray columns operating on this principle (see Section Absorption Apparatus). In the alternative version (B) the liquid is pumped through a recirculating system containing a cooler which removes the heat of absorption. If the heat of absorption is very large and the solution equilibrium is favorable, as in HCl absorption, water can be evaporated in the apparatus. The water vapor leaves the top of the apparatus and is condensed in a downstream condensation stage.

Figure 70. Absorption equipment with removal of heat of absorption

A) Removal takes place in the apparatus; B) Removal through recycling system

For certain purposes, it can be advantageous or necessary to link together different designs of apparatus or completely different processes (see Fig. 71). For high heats of absorption, as in the removal of ammonia from waste air, the stage into which the gas is fed (Fig. 71 A) should be operated in cocurrent flow with heat removal, and final purification should be carried out in countercurrent flow apparatus [593]. The flow sheet of Figure 71 B is used in, e.g., the absorption of HCl – SO_2 mixtures, where SO_2 has fairly low but nevertheless unacceptably high solubility in aqueous HCl. A stripping stage is then included in which SO_2 is removed by a stripping agent to give the required purity [594].

Figure 71. Combination of different process stages

A) Without stripping stage B) Including stripping stage

7.3.4. *Absorption Apparatus*

The apparatus described below are characterized by the largest possible interface between the gas and the liquid. In some types of apparatus, one phase is dispersed in the other. In another design, the liquid is spread over a surface to form a very thin film. This method has the advantage that only a small amount of energy is required to produce the interface, and the pressure drop is relatively low. Furthermore, the risk of entrainment of fine droplets is low, in contrast to processes in which one phase is dispersed in the other. In this case, droplet separation or demisting equipment must be included to prevent entrainment of the liquid phase in the gas stream.

Spray Absorbers. In spray absorbers (Fig. 72) the solvent is broken down into droplets by nozzles arranged in one or more planes. The momentum of the liquid is not high enough for hydraulic interactions to take place between the phases. Also, the absence of internals means that the pressure drop across the apparatus is almost zero and soiling is negligible. Spray absorbers are preferred for applications which require approximately one theoretical stage. These are mainly chemical absorption processes.

Figure 72. Spray absorber

Jet scrubbers [595] represent a further development of spray absorbers (see Fig. 73). The gas and liquid pass through the jet tube in cocurrent flow. The absorbing liquid enters the interaction space at high velocity. The gas stream is accelerated by the momentum of the liquid, and the pressure increase produced can in some cases overcome the flow resistance of the apparatus including the associated pipework. The momentum transfer also causes the liquid phase to break up into droplets, so that intensive mass and heat transfer occur. The downstream separation space is also used as receiving vessel for the pump. Generally, a demister is included at the gas outlet.

Figure 73. Jet scrubber

Jet scrubbers can be used in a multistage arrangement if several theoretical stages are necessary. This also gives the possibility of semicontinuous operation using a timed system for pumping the liquid from stage to stage. As the energy for dispersing the liquid is contained in the liquid itself as it enters the apparatus, the separating power is largely independent of fluctuations in the gas flow rate. If heat must be removed, a cooler can be included in the liquid pumping circuit.

Packed Columns. In packed columns the interface is produced by forming a film on the surface of internals (see Fig. 74 A). This enables a continuous countercurrent flow of gas and liquid to be produced. Random packings like Berl saddles, which provide a large surface for the liquid to cover, have been widely used. More recent packings are provided with holes and interior structures which not only give film formation but to some extent break the liquid up into droplets.

Figure 74. Packed column absorbers

A) For continuous countercurrent flow; B) With packings in series

For some time, packings first used in distillation technology have been widely used for absorption [597]. These consist of parallel toothed strips of various types of material. The teeth are inclined with respect to the axis of the column, and neighboring strips incline in opposite directions. Regular packings produce a considerably lower pressure drop per theoretical stage compared with random packings. Also, the minimum liquid loads are lower than with random packings. The separation effect only slightly depends of the column diameter. Both types of design require distribution devices that uniformly distribute the liquid over the cross section.

Because of the low liquid content, packed columns are not very suitable if fluctuations occur in the inlet gas velocities or in the gas concentrations. If it is not desired to use a different apparatus such as jet scrubbers or tray columns, another alternative is to use several packings in series, with recirculation (see Fig. 74 B). Fresh solvent is fed to the top of the column, and the product is withdrawn from the base. This design is relatively costly and should only be considered in special cases.

Tray columns used in absorption processes (see Fig. 75) are in principle identical to those used in distillation. A fundamental disadvantage is that typically the pressure drop in tray columns is high compared to packed columns. However, the following requirements or operating conditions can make the use of a tray column worthy of consideration:

1. In absorption processes where the loaded solvent is a useful product, high concentrations are often required. If the concentration of the component to be absorbed from the feed gas stream is low, this may mean that for mass balance reasons the necessary minimum loading of packed columns can no longer be maintained. In contrast the liquid holdup in tray columns can be reduced almost to zero.
2. With fluctuating gas flow rates or gas concentrations, a certain volume of liquid must be stored in the apparatus. This can be achieved by the use of bubble caps with chimneys. However, there is competition from other equipment, e.g., jet scrubbers.
3. A feature of the design is that contact between the gas and the liquid is concentrated on the trays. It is therefore possible to remove the heat of absorption liberated here (e.g., during the absorption of NO_x) by using tray columns fitted with cooling coils [598]. In this way, an absorption temperature that ensures optimum absorption can be maintained.

Figure 75. Tray column absorbers

Tray columns are now commercially available in all the usual construction materials, including highly corrosion-resistant versions made of graphite [599] and glass [600].

Film absorbers (Fig. 76) are used where the heat of absorption must be removed in the apparatus. The design is illustrated in Figure 76. In principle, they are heat exchangers through which the gas and liquid pass in cocurrent flow. Distributors must be included to ensure that each tube is fed with the same amount of liquid. The liquid forms a film on the inner surface of the tube, while the gas flows through the remaining interior space. The heat of absorption is removed via the outer surface of the tubes.

Figure 76. Film absorber

Film absorbers represent one theoretical stage at the most. They are therefore only used where absorption must take place at low temperature to achieve high product concentrations. In all cases, a conventional final purification stage for the gas stream must be included (e.g., a packed column).

7.3.5. *Selection of Equipment*

The various types of absorption equipment described above have preferred areas of use, depending on their characteristics. These characteristics, subdivided into process and operational parameters, are reviewed below. However, an unequivocal choice of equipment is not always possible.

Process Parameters. One important process parameter is the efficiency of separation required, expressed in terms of the number of theoretical stages. For demanding applications, packed columns or tray columns are used. Jet scrubbers are usually designed as only two or three stages, and spray absorbers in practice represent only one theoretical stage.

A further important consideration affecting the choice of apparatus is the question of heat removal. If it is possible for process reasons to remove heat by evaporation of a liquid, tray or packed columns can be used. If the temperature increase in the column leads to no phase change of the liquid, it is possible to use jet scrubbers or packed columns with exterior recirculation of the liquid through coolers. Film absorbers are also used. Tray columns having cooling devices in the trays are preferentially used in NO_x absorption.

If for reasons of mass balance the liquid flow rate is very low compared to an appreciably higher gas flow rate, the use of tray columns should be considered first. If packed columns, preferably with ordered packing, are considered, uniform distribution of the liquid over the cross section of the column is essential.

Operational Parameters. Intermittent operation with a variable total gas flow rate or variable concentrations of the substances to be absorbed should be considered first. The apparatus should be able to store a certain amount of liquid, and, the efficiency should vary as little as possible with the gas flow rate. Tray columns are highly suitable in this case. Jet scrubbers and packed columns with an external liquid circulation system can also be used, although practical problems with large number of stages must be borne in mind.

A further important operational parameter is the pressure drop across the apparatus. Jet scrubbers are a special case because they can create a pressure increase in the gas stream. The pressure drop across spray absorbers and packed columns is usually low, whereas tray columns always give rise to a high pressure drop.

7.4. Adsorption

Research into the use of porous solids for removing vapors from gas mixtures began with the construction of the first industrial plants for the production of activated prowdered carbon in 1900 to meet the demands of the sugar refining industry. The physicist J. DEWAR, who worked with activated carbon, silica gel, and aluminum oxide gel, was awarded a patent on the subject in 1905. The first process for the adsorptive removal of organic solvents from waste air and recovery by steam desorption was patented in 1916 for the Friedrich Bayer dyeing company. The use of adsorption for purifying town gas increased the importance of this gas separation technique in the 1920s. Since the 1960s, the development of adsorption catalysis and the introduction of new adsorbents have opened up further applications [601-603].

7.4.1. *Fundamentals*

In the application area considered here, adsorption means the adherence of molecules of gas or vapor (the adsorptive) to the inner surface of a highly porous solid (the adsorbent). The latter contains atoms or groups of atoms with free valencies (active centers) to which foreign molecules can become attached, and which are known as the adsorpt when in the adsorbed state. The complete boundary surface phase is known as the adsorbate (see Fig. 77). The reverse of adsorption, namely desorption, yields the desorpt and the desorption medium, which together are known as the desorbate.

Figure 77. Adsorption and desorption processes at the boundary layer

a) Adsorption, exothermic; b) Desorption, endothermic; c) Carrier gas; d) Adsorptive; e) Adsorbent; f) Inner surface (sum of pore walls); g) Adsorbate; h) Boundary surface phase; i) Adsorpt

In addition to reversible physical sorption with purely physical bonding between adsorbent and adsorptive (van der Waals forces), there is also the phenomenon of chemisorption in which stronger interaction energies cause the adsorptive to undergo chemical change, which can lead to either reversible or irreversible attachment.

The adsorption capacity of an adsorbent for a given adsorptive at equilibrium at constant temperature depends on the size and structure of the inner surface of the adsorbent and is usually represented as a function of the concentration in the carrier gas, i.e., an adsorption isotherm $x = f\,(p/p_S)_T$. Figure 78 shows the equilibrium loading x as a function of the concentration in the carrier gas, expressed in terms of the ratio of partial pressure p to the saturation pressure p_S at constant temperature T. In large-scale industrial plants attainable breakthrough or additional loadings are considerably lower for the following reasons:

- Coadsorption of other compounds, e.g., water vapor
- The shape of mass-transfer zone (adsorption zone)

– Irreversible damage of the adsorbent
– Residual load due to incomplete desorption

Theoretical adsorption isotherms can be derived from various models [604], [605]:

Figure 78. Adsorption isotherms for CS_2 at different temperatures on activated carbon

The Freundlich model

$$x = k \cdot p_i^n$$

applies to low partial pressures of the adsorptive.

The Langmuir model

$$x = \frac{x_{max} \cdot b \cdot p_i}{1 + b \cdot p_i}$$

applies to homogeneous adsorbent surface and monomolecular covering.

The Brunauer – Emmet – Teller (BET) model

$$\frac{p_i}{V(P_s - P_i)} = \frac{1}{V_{MC} \cdot C} + \frac{C-1}{V_{MC} \cdot C} \cdot \frac{p_i}{p_s}$$

applies to homogeneous surface, multilayer adsorption and capillary condensation.

The Dubinin – Raduskevic model

$$\log V = \log V_s - 2.3 \cdot \frac{RT}{\varepsilon_0 \beta} \cdot \left(\log \frac{p_s}{p_i} \right)^n$$

applies to potential theory for n = 1, 2, 3, e.g., n = 2 for adsorption of organic solvents to microporous activated carbon.

The following symbols are used in the above equations:

k, n = specific constants of the adsorptive
x = equilibrium loading of the adsorbed substance, g/100 g
x_{max} = saturation value of the isotherm for monomolecular covering, g/100 g
b = adsorptive coefficient
C = constant
p_i = partial pressure of the adsorptive, Pa
p_s = saturation vapor pressure of the adsorptive, Pa
V = adsorbed volume, mL
V_{MC} = adsorbed volume for monomolecular covering, mL
V_s = adsorbed volume at saturation pressure, mL
T = temperature, K
R = gas constant, J K^{-1} mol^{-1}
ϵ_0 = characteristic adsorption energy, J/kg
β = affinity coefficient

Figure 79 illustrates schematically the five basic types of adsorption isotherms for gases and vapors according to the IUPAC classification.

Figure 79. Basic types of adsorption isotherms

At adsorption temperatures below the critical temperature of the adsorptive, the pores of the adsorbent can become filled with liquid adsorpt. This capillary condensation increases the adsorption capacity of the adsorbent. Assuming that the

pores are cylindrical, it can be represented quantitatively by the Kelvin equation, which indicates that the degree of saturation is inversely proportional to the pore radius:

$$\ln \frac{p}{p_s} = -\frac{2\, V_M \sigma \cos\theta}{rRT}$$

The following additional symbols are used in the Kelvin equation:

p/p_S = relative equilibrium pressure

V_M = molar volume, m^3/mol

σ = surface tension adsorpt/adsorbent, N/m

θ = contact angle adsorpt/adsorbent

r = minimum pore radius, nm

As the transition from the fluid to the adsorbed phase is associated with release of energy, adsorption is an exothermic process. The enthalpy of adsorption liberated is a measure of the binding energy of the adsorpt, and this decreases as the quantity adsorbed increases. The energy required for solvent recovery is ca. 1.5 times the evaporation energy, resulting in effective temperature increases of 10 – 20 °C. The energy liberated during the complete adsorption process is known as the integral enthalpy of adsorption. The differential enthalpy of adsorption represents thermal processes at different stages of the adsorption process.

Because of the poor mechanical properties of most adsorbents, adsorption is usually carried out in a fixed bed, and the adsorption zone (mass-transfer zone) migrates through the adsorber in the same direction as the gas flow (Fig. 80). Below this zone the adsorbent is fully charged, and above it the adsorbent contains only the residual loading from the previous adsorption cycle. Within the adsorption zone, mass transfer takes place until equilibrium between the adsorbed phase (adsorpt) and the adsorptive concentration in the gas phase is reached. In adsorbents with wide pores, these complex processes are controlled less by mass transfer than is the case with adsorbents with narrow pores.

Figure 80. Loading profile in a fixed-bed adsorber

In practical applications, the waste gases to be purified often consist of a carrier gas containing mixtures of substances from which one or more components must be selectively removed. Separation can be achieved by utilizing the following effects:

1. Variation in the affinity of the adsorbent for the various gaseous components, this being apparent from the adsorption isotherms (equilibrium effect)
2. Differences in the critical molecular diameters of the adsorptives, enabling separation to be carried out if the effective pore diameter of the adsorbent (molecular sieve) is greater than that of the molecules of the component to be selectively adsorbed and smaller than those of the carrier gas (steric effect)
3. Different rates of diffusion of the adsorptives through the boundary layer and the pore structure to the active centers (kinetic effect)

Industrial adsorbents are regenerated when the breakthrough of the adsorptive occurs. Regeneration involves driving off the adsorpt as a gaseous or liquid phase (desorption), and drying and/or cooling treatment to restore the adsorbent to the optimum condition for reuse. Table 20 lists industrial regeneration methods. In waste-air purification the temperature-swing process is usually applied. The regeneration method and equipment have a major influence on the plant concept and investment and operating costs.

Table 20. Industrial regeneration methods

Method	Features	Typical applications
Temperature-swing desorption	desorption with slightly superheated steam, inert gas, or electrical energy (resistance heating of graphitic activated carbon or induction heating) up to 300 °C followed by cooling to adsorption temperature, if necessary after drying	purification of process gas, solvent recovery
Pressure-swing desorption	desorption by total pressure reduction between adsoption and the desorption steps, sometimes combined with purge gas feeding	separation of permanent gases, e.g., O_2 separation from air; CH_4 separation from

		water, hydrogen, or biogas
Extraction	a. with liquid solvents which are subsequently desorbed by the temperature-swing process (with steam) b. with NaOH followed by water wash and drying c. with supercritical CO_2	a. extraction of sulfur with carbon dioxide b. phenol-contaminated activated carbon from water purification c. activated carbon loaded with organic compounds
Wet oxidation	heating of the loaded and water-saturated adsorbent under pressure (p > water vapor pressure) with air feeding	spent activated carbon from drinking-water treatment

As it is not possible to drive off the adsorpt completely at acceptable cost, a residual loading is left behind, reducing the capacity of the adsorbent. If side reactions occurring during adsorption or desorption change the chemical structure of the adsorpt such that the residual loading increases, it is still often possible to reactivate the adsorbent in a separate plant. The process conditions for this treatment correspond to those of activation, i.e., the adsorpt is removed by oxidation. For activated carbons, this involves a selective gas treatment of the adsorbents with water vapor or CO_2 at 700 – 900 °C without appreciably changing the carbon structure. Oxidic adsorbents are regenerated with hot air.

7.4.2. *Industrial Adsorbents*

The adsorbents used in gas technology are not usually finely divided, but are highly porous granules or fibers with a large inner surface on which the foreign molecules become concentrated. Depending on the raw material and method of manufacture, they have different adsorption properties, which can be classified according to the following criteria:

The extent of the inner surface formed by all the pore walls is the main factor determining the adsorption capacity. It may be determined by the method of DIN 66 131 (BET method) [606], which is based on the adsorption isotherm for nitrogen at its boiling point and the space required by nitrogen molecules for monomolecular occupancy. The method is valid only for isotherms of types II and IV (Fig. 79).

The pore structure is important for the diffusion of the adsorptive to the active centers of the inner surface. Unlike molecular sieves, in which the inner cavities are linked by pores of uniform diameter, other adsorbents have a wide spectrum of pore size (Fig. 81). The pore radii (assuming a cylindrical shape) determined by different methods depending on the pore diameter (macropores: mercury intrusion porosimetry; mesopores and micropores: Kelvin equation) can extend over several orders of magnitude, and are classified according to the IUPAC Standard into

macropores	$d > 50$ nm
mesopores	$50 > d > 2$ nm
micropores	$2 > d > 0.4$ nm
submicropores	$d < 0.4$ nm.

The pore radii distribution of meso- and micropores is normally determined by evaluating the desorption profile of an isotherm, and that of macropores by mercury intrusion porosimetry.

Figure 81. Differential pore distribution of carbonaceous adsorbents

The porosity is the pore volume as a fraction of the adsorbent volume, or per gram of adsorbent.

The adsorption characteristic of an adsorbent is revealed by the isotherms obtained with different adsorptives. It yields important information on the concentration dependence of the adsorption properties and the establishment of equilibrium.

The hydrophobicity or hydrophilicity of an adsorbent often determines whether it can be used in waste-gas purification, because water vapor is usually present at a considerably higher concentration than the substances to be removed. Figure 82 shows the different adsorption behaviors of some important adsorbents for water and toluene as typical examples for polar and nonpolar adsorptives.

Figure 82. Adsorption isotherms for water (A) and toluene (B)

a) Activated carbon; b) Activated alumina; c) Molecular sieve, hydrophilic; d) Silica gel; e) Zeolite, hydrophobic; f) Polymeric resin

The selectivity of an adsorbent can be a result of chemical effects (hydrophobicity, hydrophilicity) or steric effects (similarly shaped pore openings through which only molecules smaller than a particular diameter are able to penetrate).

Catalytic properties resulting from the chemical constitution of the inner surface may enable certain tasks to be performed, but can also lead to undesired side reactions and irreversible formation of chemical bonds (oxidation, polymerization, hydrolysis).

The industrial adsorbents can be divided into the categories shown in Table 21 in accordance with the raw materials and treatment methods used in their production.

Table 21. Industrial adsorbents

Adsorbent	Specific surface, $m^2\ g^{-1}$	Specific heat, $J\ kg^{-1}\ K^{-1}$	Compacted apparent density, $kg\ m^{-3}$	Typical applications
Activated carbons				
fine-pored	1000 – 1200	850	400 – 500	waste-air treatment, deodorization, separation of low-boiling substances
medium-pored	1200 – 1400	850	350 – 450	solvent recovery, adsorption of medium-boiling substances
wide-pored	1000 – 1500	850	300 – 400	adsorption of high-boiling substances
Activated coke	<400	850	500 – 600	separation of dioxines, furanes, SO_x and NO_x
Carbon molecular sieves	<100	1000	620	nitrogen and oxygen separation, methane adsorption from biogas
Aluminum oxide	100 – 400	920	700 – 800	desulfurization of gases
Silica gel				
fine-pored	250 – 350	920	700 – 800	deodorization, gas dehydration
wide-pored	600 – 850	920	400 – 800	adsorption of hydrocarbons
Molecular sieve				
zeolites				
hydrophilic	500 – 1000	900	600 – 800	gas dehydration, fractionation of hydrocarbons
hydrophobic	500 – 700	900	400 – 500	waste-air treatment, solvent recovery, solvent upgrading
Polymer adsorbents (styrene – divinylbenzene resins)	1000 – 1500	350	300 – 400	solvent recovery, gasoline recovery

The activated carbons (⟶ Carbon – Activated Carbon) are hydrophobic adsorbents with a wide range of specific surface areas, pore structures, and pore volumes, over 90 % of which consist of carbon with a graphitic crystal structure. They are produced in the form of shaped, powdered, and fibrous activated carbon from raw materials of vegetable origin by low temperature carbonization (primary carbon), grinding, shaping, and activation, and play a major role in the adsorptive purification of waste gas.

Activated coke is an adsorbent produced from finely hard coal preoxidized with air, shaped using pitch as a binding agent, and activated by treatment with gas (CO_2, H_2O). The inner specific surface area, pore volume, and porosity so produced do not reach the figures typical of activated carbons.

Coke produced by the low temperature carbonization of lignite from the Rhine region in a hearth type furnace contains up to 87 % carbon. Its adsorptive and catalytic properties enable the gaseous impurities Hg, SO_2, HCl, HF, Cl_2, NO_x, dioxins and furans to be efficiently removed. This cheap material is not regenerated and is used as a crushed or powdered adsorbent to remove small quantities of impurities.

Carbon molecular sieves have micropores with diameters of 0.3 – 1.0 nm. These very narrow pores mean that these adsorbents cannot be used for emission reduction.

Activated aluminum oxide (> 99 % Al_2O_3), an oxidic hydrophilic adsorbent, is mainly used for removing sulfur compounds.

Molecular sieve zeolites are crystalline aluminum silicates with an SiO_2 – Al_2O_3 lattice. They contain cavities linked by pores of uniform diameter, so that their adsorption capacity combined with their steric separating effect can be used in gas purification. If a high proportion of Al_2O_3 is replaced by SiO_2, this gives a hydrophobic zeolite (trade name: Wessalith DAY) [607] suitable for selectively adsorbing organic components and mercury from waste gases with a high moisture content, and is therefore known as “white activated carbon”. As it is a mineral, it can be regenerated at high temperatures with air.

Spheroidal adsorber resins made of nonpolar macroporous polymers are produced by polymerization of styrene in the presence of a cross-linking agent, and have the advantage of ease of regeneration at low temperatures when used for the purification of solvent-containing waste air. They also have a low affinity for water vapor.

In silica gels, the SiO_2 particles form a continuous crystalline structure containing pores. Silica gels with small pores are used as drying agents, while the wide-pore types are suitable for removing hydrocarbons from waste gases.

The properties of some adsorbents can be modified by impregnation with organic or inorganic substances (Table 22) to give additional separation effects (e.g., the adsorption of H_2S by activated carbon impregnated with potassium iodide).

Table 22. Reactions of impregnated activated carbon with contaminants of a gas stream

Contaminant	Impregnating agent	Active substance	Conversion
Ammonia	copper	$CuSO_4 \cdot 5\,H_2O$	$CuSO_4 \cdot 5\,H_2O + 4\,NH_3 \longrightarrow [Cu(NH_3)_4]SO_4 + 5\,H_2O$
Arsenic hydride	silver, zinc	Ag, Ag_2O, ZnO, Na_2ZnO_2	$2\,AsH_3 + 3\,O_2 \longrightarrow As_2O_3 + 3\,H_2O$
Hydrogen cyanide	copper	CuO, Cu_2O	$2\,HCN + Cu_2O \longrightarrow 2\,CuCN + H_2O$
	zinc	ZnO, Na_2ZnO_2	$2\,HCN + ZnO \longrightarrow Zn(CN)_2 + H_2O$
Phosgene	copper	CuO, Cu_2O	$COCl_2 + CuO \longrightarrow CuCl_2 + CO_2$
	zinc	ZnO, Na_2ZnO_2	$COCl_2 + ZnO \longrightarrow ZnCl_2 + CO_2$
Mercury	sulfur	S_8	$Hg + S \longrightarrow HgS$

The following are the principal criteria used when selecting an adsorbent for waste-gas purification:

1. High selectivity with fast kinetics for the component to be removed
2. High adsorption capacity even at low concentrations
3. Ease of desorption
4. Stability towards temperature change and chemical attack
5. Hydrophobicity and attrition resistance

The design of an adsorption plant for waste-gas treatment depends not only on the type of adsorbent but also on some properties of the substances to be removed. The design engineer should pay attention to the aspects listed in Table 23.

Table 23. Properties of substances to be removed and associated design measures

Pollutant properties	Design aspects
Molecular mass	adsorption capacity generally increases with increasing molecular mass
Boiling point or boiling range	adsorbability increases with increasing boiling point
Wetting ability	the surface tension of the component to be adsorbed must allow good adsorbent wetting
Molecular structure	its significance depends on the pore structure of the adsorbent
Critical temperature	increasing the adsorption capacity by capillary condensation is only possible if the operating temperature is below the critical temperature of the adsorptive (condensation cannot take place at supercritical temperatures)
Desorbability	frequently the equipment and process steps needed for desorption determine the system configuration and economics

Water solubility	crucial factor in steam desorption, may entail process steps for recovering a water-free desorpt or a hot-gas desorption process
Corrosion behavior	governs material selection
Explosion limits	determine safety measures

7.4.3. *Design Criteria for Adsorbers*

To enable the gas that is to be purified to pass through the adsorbent bed as effectively as possible, the latter must be arranged as a fixed bed, moving bed, or other arrangement in the adsorber. The dimensions of the equipment are determined by the maximum permissible flow rate of the waste gas and bed depth of the adsorbent. For adsorbents in powder form, fluidized beds or entrained flow systems give intensive contact with the adsorptive. Most adsorbers are of the fixed-bed type, because of the poor mechanical stability of the adsorbents. The gas velocity is about 0.5 m/s with respect to the free cross section and should be well below the velocity at which the granules in the upper region of the bed will be in motion. With most activated carbons, this velocity is 0.8 m/s for the carrier gas air at ca. 20 °C. In some cases, the adsorption and/or reaction rates make the residence time decisive, which can lead to larger adsorber cross sections or/and bed depth.

Flow resistance figures for various granular adsorbents under normal gas velocities are shown in Figure 83. They depend on the properties of the fluid phase (density, viscosity, velocity) and of the adsorbent bed (grain size, grain shape, surface area, voids fraction). The calculation method often quoted in the literature [608] also contains an experimentally determined resistance number. Uniform flow through the bed not only gives optimum utilization of its adsorption capacity, but tends to give efficient heat removal, preventing hot spots which can lead to spontaneous ignition of carbonaceous adsorbents. Equipment for monitoring CO in the impure and purified gas serves as a warning device. Bed temperature measurements provide inadequate warning owing to the poor heat-transfer properties.

Figure 83. Pressure drop for various adsorbents (p = 1 bar abs.; T = 20 °C)

a) Activated carbon cylinders, 3 mm; b) Activated carbon cylinders, 4 mm; c) Zeolite cylinders, 4 mm

For a given diameter, the bed depth of the adsorber depends on the amount of adsorption medium charged. This is usually determined from the equilibrium loading, after subtraction of factors that reduce the capacity such as residual loading and irreversible damage. This lowers the operating capacity of the adsorbent to a fraction of the total loading at equilibrium. In solvent recovery by activated carbons, this fraction is ca. 30 %. Moreover, a minimum bed depth must be provided to accommodate movement of the adsorption zone. This also ensures minimum pressure drop required for uniform gas distribution.

The effective bed depth can be derived from the profile of the adsorption zone [604], [605]. As the adsorption zone usually migrates through the bed at constant velocity in the same direction as the gas flow, breakthrough curves determined at the same flow rate in experimental adsorbers can be transferred to large-scale industrial plants. In breakthrough curves, the ratio of the concentration of the adsorptive at the exit of the adsorber to that at the inlet (c/c_0) is plotted as a function of adsorption time t. As shown in Figure 84, for bed depths h_1 and h_2, the half-value times t_{h_1} and t_{h_2} (where c/c_0 = 0.5) are determined. This gives the migration rate u of the adsorption zone:

$$u = \frac{h_2 - h_1}{t_{h_2} - t_{h_1}}$$

Multiplication by the time interval $t_2 - t_1$ gives the length h_z of the adsorption zone:

$$h_z = u(t_2 - t_1)$$

Assuming a symmetrical profile of the adsorption zone, the effective height h_{eff} of the bed is given by $h_{eff} = h - 0.5\, h_z$. The amount of adsorbate x (t) taken up by the adsorbent from the carrier gas $\dot{V}$ up to time t is given by

$$x(t) = \frac{\dot{V}}{m}\int_0^t (c_0 - c_t)\mathrm{d}t$$

Figure 84. Determination of effective bed depth from breakthrough curves

Other methods are described in the literature [609], [610] for dimensioning an adsorber under given conditions from mass and energy balances.

The design of the adsorber calculated from adsorption criteria must also be suitable for the regeneration conditions, and this must be investigated separately.

7.4.4. *Adsorber Designs*

Specific types of adsorber have been developed for the various tasks of waste-gas purification [611]. These can be divided into fixed-bed and moving-bed equipment, and special designs (Fig. 85).

Figure 85. Types of adsorber

A) Fixed-bed adsorber

a) Raw gas; b) Clean gas; c) Desorption medium; drying and cooling medium; d) Desorption medium and desorpt; e) Carrier grid; f) Intermediate layer; g) Adsorbent packing

B) Rotating adsorber

a) Raw gas; b) Clean gas; c) Adsorbent; d) Desorption segment; e) Cooling segment

C) Fluidized-bed adsorber

a) Raw gas; b) Clean gas; c) Adsorbent, regenerated; d) Adsorbent, loaded; e) Fluidized bed; f) Down pipe

D) Moving-bed adsorber

a) Raw gas; b) Clean gas; c) Adsorbent, unloaded; d) Adsorbent, loaded; e) Moving bed

E) Countercurrent adsorber

a) Raw gas; b) Clean gas; c) Adsorbent, unloaded; d) Adsorbent, loaded; e) Moving ded

F) Entrained-flow adsorber

a) Raw gas; b) Clean gas; c) Adsorbent, unloaded; d) Adsorbent, partially loaded; e) Adsorbent, transferred outward; f) Tubular reactor; g) Woven filter

Because of the poor mechanical properties of most adsorbents, the fixed-bed design (Fig. 85 A) is usually used in industrial plants. This consists of a random packing on a carrier grid covered with perforated sheet, woven steel wire, or a perforated ceramic plate. Vertical or horizontal adsorbers may be preferred depending on the type of waste gas to be treated and the space available on site. In the vertical designs, the adsorbent is sometimes contained in a ring-shaped shaft to save floor space. Even for longer service life of the adsorbent, the apparatus should include equipment for rapid charging and emptying. If desorption with water vapor is used, the adsorber must be designed as a pressure vessel.

Moving-bed adsorbers (Fig. 85 D) are almost always designed vertically to save floor space and to facilitate the demands made on the mechanical charging and discharging equipment. Virgin or regenerated adsorbent is fed from above while the same amount of exhausted material is removed from below. Locks are provided if necessary at both feed and discharge points. Slotted walls or screens are provided at the gas inlet and outlet sides to guide the adsorbent bed. The bed can be subdivided into several layers arranged in series, containing different adsorbents with different functions which can be moved at different rates. The mechanism for removing the adsorbents must ensure that they move downwards as a single mass, including the edge regions. In another design, a circular moving bed is used through which the gas flows from the inside to the outside or vice versa. In the design illustrated in Figure 85 E, the waste gas is routed through the adsorber in countercurrent flow to the moving bed.

The fluidized-bed technique (Fig. 85 C) requires hard adsorbent granules with high abrasion resistance, which has considerably restricted the use of this method. The apparatus contains a perforated sheet or nozzle tray on which the adsorbent is maintained in a fluidized state by the waste gas entering from below. The adsorbent passes from the inlet to the outlet perpendicular to the gas flow. The purification effect can be increased by using several fluidized beds in series. Like scrubbing columns, they are equipped with inlet and outlet weirs and are connected by down tubes. The comparatively small amount of adsorbent makes the removal of some gaseous components difficult, and the additional loading capacity of the adsorbent is lower than that obtainable with fixed beds. An advantage is the continuous operation of the adsorption and regeneration stages.

Continuous operation is also achieved by rotating adsorbers (Fig. 85 B). The rotor has a large specific surface area formed by granular activated carbon or ceramic trays which carries a layer of finely divided activated carbon or fibrous carbon. The rotor rotates round a horizontal or vertical axis inside a housing, passing through the adsorption, desorption, and cooling zones successively. The gas can pass through the rotor axially or radially. Because desorption is carried out with hot air at a flow rate that is only a fraction of that of the waste gas, the adsorber is not suitable for the final purification stage, but

only for a preliminary increase in concentration.

In the entrained-flow system (Fig. 85 F), the adsorbent powder is carried by the flow of waste gas. The main function of the apparatus is to provide a mixing space, while the adsorption of the impurities mainly takes place on a woven filter downstream.

Some special designs of adsorbers include adsorbent mats made of activated carbon fibers, filter elements in which activated carbon granules are bonded together, or powdered activated carbon bonded to highly porous carriers such as polyurethane foam.

7.4.5. *Plant Concepts*

Apart from those plants intended purely for waste-gas separation, in which no regeneration is provided for or possible because of the long service life of the adsorbent (several months), the concept of an adsorption plant for waste-gas purification is very much influenced by the regeneration method. Regeneration can be achieved in various ways (see Table 20).

Steam desorption, which exploits the temperature dependence of the adsorption equilibrium and the high heat of condensation of the steam, is the most widely used process for solvent recovery (Fig. 86). The adsorber is heated with slightly superheated steam at ca. 150 °C, which also acts as a purging medium. The condition and consumption of steam (3 – 5 kg/kg solvent) depend mainly on the type of adsorptive and the desired residual loading of the adsorbent, according to the required purity of the waste gas. The desorbate produced, consisting of solvent vapors, steam, and condensate, is condensed, cooled, and separated. If the solvent is immiscible with water, the separation equipment used is based on density difference. As a rule of thumb the higher the mutual solubility of solvent and water, the more complex separation process, and a rectification column may even be required. An overview of methods used for processing the desorbate is given in Figure 87. After desorption, the adsorber is dried and cooled with purified waste gas or clean air to the temperature of the adsorption step. As the cooling gas contains small quantities of solvent it is passed through the operating adsorber to prevent emission peaks. This alternating adsorption/desorption system means that there must be at least two adsorbers to ensure continuity of the waste-gas purification process.

Figure 87. Methods of processing desorbates

In special cases, an inert gas or air is used to heat the adsorber directly. This can be carried out in three ways (Fig. 88). The closed-loop system (Fig. 88 A) is advantageous if enough of the desorbed substances can be condensed to ensure that their residual partial pressures do not cause an unacceptably high residual loading. Otherwise, if oxygen-free waste gases are being purified or a noncombustible adsorbent is used, regeneration can be carried out in an open loop (Fig. 88 B). Here a certain amount of the purified waste gas is fed through the adsorber being cooled and that being heated, and, after partial condensation of the desorbed substances, passed into the impure gas and thus into the adsorber during the adsorption cycle. If the desorbed substances cannot be adequately condensed, or if they consist of a mixture of substances whose recovery is not feasible, a recirculation system cannot be used, and the desorpt is then treated by thermal or catalytic combustion. In this case, the adsorption plant functions as a concentration plant, using preheated air for desorption (Fig. 88 C).

▷ ◁ = Open valve; ▸ ◂ = Closed valve

Desorption by pressure reduction (pressure-swing process) requires a significant pressure difference between the adsorption and the desorption steps so that desorption has to be carried out under vacuum combined with a small purge gas stream which carries the desorpt out of the adsorber.

In a few special cases, e.g., sulfur-loaded carbon treated with CS_2, desorption is carried out by solvent extraction, after which the solvent is desorbed by steam.

Plant sizes range from compact plants with throughputs of a few hundred m^3/h to large plants in which waste gas can be purified at a rate of several hundred thousand m^3/h.

7.4.6. *Adsorption Processes*

The availability of several adsorbents with various physical, chemical, and mechanical properties in association with the wide range of waste-gas purification tasks has led to the development of a variety of industrial techniques.

In the oldest application — the recovery of organic solvents from waste air — the most widely used processes are based on fixed beds of activated carbon (see Fig. 85). The waste air is extracted from hooded production areas conditioned by cooling, partial condensation of the water vapor and heating to reduce the relative humidity in order to minimize coadsorption of water and then fed at ca. 40 °C to the adsorber on loading duty. At an approach velocity of ca. 0.5 m/s it passes upwards through the activated carbon bed, which has a height of 0.8 – 1.5 m. The granular adsorbent takes up the solvent vapors, and the purified waste air passes out of the adsorber. After the solvent breakthrough limit has been reached, the adsorption process is interrupted, after the freshly regenerated adsorber has taken over the purification of the waste air. The solvent is then desorbed by passing superheated steam downwards through the activated carbon. The steam heats the bed to > 100 °C and carries away the desorpt. The desorbate is condensed, cooled, and passed to the gravity separator. This is a settling vessel in which the mutually insoluble organic and aqueous phases separate as a result of the density difference. Approximately 4 kg steam/kg solvent is required for this process step, which accounts for most of the operating costs. The subsequent drying and cooling steps are carried out with purified waste air or clean air, which are then cleaned by passing them through the adsorber on operating duty. If the recovered solvent is miscible with water, fractional distillation may be required.

If the time required for regeneration is appreciably shorter than that for adsorption, higher loading of the activated carbon can be achieved. In this case, the regenerated adsorber can be connected after the operating adsorber (two-stage adsorption). The waste air passes through the two vessels connected in series, the first adsorber being charged beyond breakthrough.

In activated carbon plants using hot gas desorption, the operation must be performed by purging the loaded adsorbent with an inert gas in a closed circuit, consisting of a cooler-condenser and separator, a heater, and a drying stage for the regeneration gas (see Fig. 88 A).

With the hydrophobic zeolites used for removing solvents from waste air, dry desorption with hot air can be used, preferably in a closed recirculating system, provided that partial condensation of the solvent is sufficient for reuse of the waste air in, for example, a drying process.

Polymer adsorber resins loaded with solvents can be regenerated at temperatures as low as 80 °C, either by steam or hot gas [612]. They are typically employed in moving-bed applications (Fig. 89, and permit continuous operation of fluidized bed adsorbers in combination with moving-bed regenerators (e.g., Polyad process) [612].

Figure 89. Continuous adsorption system for recovery of solvent from exhaust air

a) Fluidized-bed adsorber; b) Moving-bed regenerator; c) Raw-gas blower; d) Condenser; e) Separator; f) Blowers

The Kontisorbon process for continuous adsorption and desorption (Fig. 90) [613] uses attrition-resistant activated carbon beads of diameter 0.7 mm in a multistage fluidized bed, maintained in the fluidized state by waste air at a velocity of 0.8 – 1.2 m/s. The carbon is regenerated by feeding it into a heat exchanger with vertical tubes underneath the adsorber. Indirect steam heating in combination with nitrogen purging drives off the solvent, which is partially recovered as condensate. The remaining solvent is adsorbed from the nitrogen purge cycle by the activated carbon above the desorber which has passed through the fluidized bed. Cooling of the activated carbon after desorption is also indirect. It is then pneumatically returned by air lift to the upper perforated tray of the fluidized bed.

Figure 90. Kontisorbon process

a) Adsorbent, regenerated; b) Fluidized bed; c) Inert gas; d) Fan; e) Separator

Rotary adsorbers also enable the process to be operated continuously. The rotor is packed with granular activated carbon or consists of a ceramic honeycomb structure coated with fine-grained activated carbon or fibrous carbon. It rotates round its horizontal axis in a housing at 1 – 2 rpm passing through an adsorption zone, a desorption zone, and a cooling zone in succession (Fig. 85 B). The waste air passes through the adsorption segment at 1 – 2 m/s, the pressure drop being only 2 – 3 mbar [614]. Desorption can be carried out with steam, but preferably by hot air at a flow rate of 2 – 20 % of the waste gas flow rate. This passes out of the plant as higher concentrated secondary waste air and requires purification.

The plant concept to clean waste air from e.g. gasoline tanks with high concentration of organic vapors up to saturation involves a scrubber or a membrane unit combined with a downstream pressure-swing adsorption plant.

For the removal of low-boiling and medium-boiling hydrocarbon vapor mixtures, pressure-swing adsorption with activated carbon is followed by an absorption stage to treat the compressed gases from vacuum desorption with gasoline as scrubbing liquid, which can be returned to the tank farm.

In another option the hydrocarbon-saturated air is freed from the bulk of its vapor load by a membrane permeation stage operated at a pressure of 3 – 4 bar. The recovery efficiency depends on the specific permeation rates of the organic compounds. The resulting concentrated mixture of organics can then be condensed.

For final abatement of the hydrocarbons the exhaust air leaving the membrane system enters a pressure-swing adsorption unit, which consists of two alternately operating parallel lines, each equipped with two fixed-bed adsorbers in series. The first is packed with activated carbon to retain higher boiling hydrocarbons while the downstream apparatus contains molecular sieves for adsorbing low-boiling organics. The desorbate air stream is returned to the front end of the treatment system and mixed with the raw gas.

Sulfur compounds are removed from waste gases using either activated carbons or activated aluminum oxide as the adsorbent or adsorption catalyst. In the Sulfosorbon process [615] for purifying waste air containing H_2S and CS_2 from the viscose process, each adsorber is usually packed with two layers of activated carbon having two different effects. The lower part of the bed consists of wide-pore carbon impregnated with potassium iodine, which catalyzes oxidation of the H_2S and adsorbs the elemental sulfur formed. Oxidation to sulfuric acid is largely prevented. The CS_2 is removed mainly in the upper bed of narrow-pore activated carbon. As soon as the CS_2 concentration in the purified waste air exceeds the limit value, a regenerated adsorber takes over the purification process, and after purging with an inert gas, desorption of the CS_2 by steam at 110 – 130 °C commences. The organic and aqueous phases are separated in a gravity separator. Regeneration of the lower, sulfur-loaded bed is required only in intervals of several months and comprises the following process steps: water washing to remove sulfuric acid and/or ammonium sulfate formed as side products, extraction of the elemental sulfur with CS_2, separation of sulfur and CS_2 by distillation, desorption of CS_2 with steam, and drying and cooling the adsorber with air.

The Thiocarb process [616] developed for the same purpose uses a single bed of wide-pore activated carbon with a very low metal content (to suppress the catalytic formation of H_2SO_4). Any acid which is formed despite this is neutralized by adding NH_3. The regeneration process is as described above.

The Sulfacid process [617] can be used with SO_2-containing, dust-free process waste gases using activated carbon as an adsorption catalyst to purify the gas in a fixed bed, provided the O_2 content is sufficient to convert SO_2 and water to sulfuric acid. Washing with water yields dilute H_2SO_4 (10 – 15 %), which can be concentrated to ca. 30 % in combination with the waste-gas cooling in the venturi scrubber. For SO_2 concentrations of 0.1 – 1.0 vol % the removal efficiency is 90 – 95 %.

Desulfurization and removal of nitrogen oxides from combustion waste gases is carried out in the BF – Uhde process [618] by adsorption catalysis at 120 – 150 °C on 6 mm activated coke in a two-stage moving-bed reactor with transverse gas flow (Fig. 91). As well as desulfurization, the first passage of the gas also removes HCl and HF. Ammonia is then added to convert the nitrogen oxides to N_2 and H_2O by selective catalysis in the second passage of the gas, through the upper part of the reactor. Ammonium sulfate is formed in side reactions. Regeneration is carried out by indirectly heating the dedusted activated coke to ca. 450 °C, and a gas with a high SO_2 content is formed by reaction of the sulfuric acid with the carbon to give a SO_2 rich gas which can be converted to sulfuric acid, elemental sulfur or liquid SO_2.

Both activated carbon and activated aluminum oxide catalyze the Claus reaction

$$2\,H_2S + SO_2 \rightleftharpoons 3S + 2\,H_2O$$

at ca. 130 °C and readily adsorb the sulfur formed. This is the basis of the Sulfreen process [619] for desulfurizing Claus waste gases. In the single-stage process (Fig. 92), a fixed bed of activated aluminum oxide gives removal efficiencies of 80 – 93 %, depending on the inlet concentration of H_2S and SO_2. During desorption by heated clean gas at ca. 300 °C, most of the sulfur driven off can be condensed from the recirculating gas stream. Clean gas is also used for cooling to the adsorption temperature. For higher efficiencies, the two-stage variant (the Carbosulfreen process) includes an activated carbon bed in which H_2S reacts with O_2, and the elemental sulfur formed is adsorbed. Preliminary catalysis by titanium dioxide allows COS and CS_2 to be hydrolyzed to H_2S (Hydrosulfreen process).

Figure 92. Sulfreen process

a) Adsorption (adsorber); b) Regeneration (adsorber); c) Regeneration gas; d) Condenser/cooler; e) Separator; f) Fan; g) Heater

Another important application of adsorption is the removal of heavy metals (in particular mercury vapor) as well as dioxins and furans from the flue gases from incineration plants for municipal waste, hazardous waste, and sewage sludge. Adsorbents used include activated carbon, activated coke, hearth-furnace coke, and hydrophobic zeolites. The efficiency of removal of mercury by activated carbon or zeolites can be considerably improved by impregnation with sulfur or sulfuric acid, and the same effect is produced by SO_2-containing flue gases. The long residence times required are a disadvantage, requiring the use of high-volume vertical adsorbers [620]. The exhausted adsorbent is removed discontinuously or continuously, and is often used as a fuel in combustion plants. The pollutants are recovered by means of dedusting filters or washing processes (Hg, $HgCl_2$, SO_2, HCl, and HF) or are incinerated (dioxins and furans). A further alternative for oxidic adsorbents is thermal regeneration, which can be more cost-effective than combustion in the case of expensive adsorbents [621]. If the space for large fixed-bed filters is not available, powdered hearth-furnace coke can be added to the wash suspension for desulfurization. High removal efficiencies have been obtained using powdered hearth furnace coke and lime in a pilot plant consisting of a fluidized-bed reactor and fabric filter in an hazardous-waste incineration plant (Fig. 93) [622]. The results correspond to those obtained on a full-scale plant for treating flue gases from municipal waste incineration operating on almost the same principle [623].

Powdered carbonaceous adsorbents injected in entrained-flow systems and separated downstream by fabric filters are gaining increased significance in removing heavy metals, dioxins and furans from waste gases and hazardous waste incineration plants, steel production plants, recycling plants for Pb- and Zn-containing filter dust, sintering plants and other processes. They collect those substances from the off-gas streams at high selectivity in spite of their low concentrations [624-626]

Natural zeolites boast the advantage of greater safety in operation. This means that the safety equipment normally required, addition of limestone, extinguishing facilities, measuring and control devices etc. can be omitted. There is no self-ignition hazard [627].

Circulating fluidized bed pilot plant tests with natural zeolites have demonstrated that nitrogen oxides can be successfully converted to nitrogen and water by selective catalytic reduction.

7.4.7. *Recycling and Disposal of Spent Adsorbents*

Depending on the type of adsorbent, the following alternatives are available for recycling or disposal of spent adsorbents:

1. Reactivation of carbon-based and oxidic adsorbents with recovery of the adsorbed substances, if possible
2. Hydrogenation of carbon-based adsorbents and polymer adsorber resins, together with other organic wastes such as spent oils, paint sludge, plastics, and solvents to produce base stocks for the oil industry
3. Co-burning of carbon-based adsorbents in the combustion plant producing the flue gas
4. Co-burning of carbon-based adsorbents and polymer adsorber resins in hazardous-waste incineration plants;
5. Disposal of oxidic adsorbents

Figure 94 shows a reactivation plant for treating granular activated carbons from waste-gas cleaning and drinking-water treatment loaded with organics. Instead of a rotary kiln a multistage reactor or fluidized-bed reactor may be installed in which a reducing atmosphere is maintained. With carbon retention time in the kiln of ca. 15 min and 800 °C operating temperature, the gasification losses amount to ca. 5 % including losses due to mechanical and thermal stresses (undersize). During the heating step the reversibly adsorbed substances are desorbed. The irreversibly bound compounds are removed by selective gasification with water vapor and carbon dioxide, which to a certain extent changes the pore structure. The waste gases of the reactivation process are cleaned by thermal oxidation of the pollutants in the incinerator and passage through a downstream caustic scrubber. The adsorption power of oxidic adsorbents can be restored by controlled oxidation with air or oxygen fed to the adsorber at high temperature.

7.5. Biological Processes

7.5.1. *Overview and Classification*

In biological methods for purifying waste gas, the hazardous and/or odorous constituents are reacted or degraded biologically. This does not take place in the waste gas itself, but after the materials to be treated have been sorbed by solids or liquids in the biological purification equipment. This equipment can be classified according to the process used for conversion or reaction as follows:

1. Biofilters containing organic and inert materials
2. Bioscrubbers containing fixed or suspended microorganisms
3. Combined processes in which biofilter and bioscrubber units are arranged in series.

The selection of the process to be used depends on several criteria which must be considered in each individual case [628].

7.5.2. *Process Engineering Principles*

To correctly operate and optimize a process, biological, physical, and chemical effects have to be considered. The main process engineering task is to establish and maintain optimum living conditions for the microorganisms.

7.5.2.1. *Biological Conditions*

Microorganisms are so-called destruents, which break down organic materials such as carbohydrates, fats, and proteins into their basic components (CO_2, CH_4, NO_3^-, PO_4^{3-}, etc.). These components are then used by the microorganisms to form their own biomass. The required energy is derived from the biochemical oxidation (i.e., the degradation of the organic substances). Microbial degradation is therefore associated with an increase in the biomass. If the required carbon is derived from an organic substance, the term “heterotrophic habit” is used. Most gaseous substances are available to microorganisms, although their biodegradability properties can range from easy to very difficult, depending on their chemical structure.

Inorganic gaseous compounds such as ammonia and hydrogen sulfide can also be used by microorganisms as sources of energy or as nutrients. The carbon required for growth is derived from atmospheric carbon dioxide (carbon autotrophism) [629].

There are ca. 3500 naturally occurring microorganisms which, together with specialized lower life forms, make it possible to break down even difficultly available substances. The microorganisms are either sessile (i.e., attached to organic filter materials or inert packings) or suspended freely in a scrubbing liquid. In both cases, the gaseous substances must be absorbed in a liquid to make them available for degradation.

The following conditions must be fulfilled to enable the equipment to function:

1. The components of the waste gas must be biologically degradable
2. The waste gas must not contain substances toxic to microorganisms
3. The components of the waste gas must be soluble in water
4. The products formed by the microorganisms must not have a detrimental effect on the biological degradation process.

The conditions in the medium must be optimized for the microorganisms. In biological processes, the following factors affect growth:

Oxygen Demand. In most waste gases not derived from purely chemical processes, sufficient oxygen is present to enable processes based on fixed microorganisms to be used. In bioscrubbers which use suspended microorganisms, adequate amounts of oxygen must be added at the regeneration stage.

Water Demand. Living microorganisms contain 75 – 85 % water, which is needed to transport nutrients into and metabolic products out of the cells. Thus they have a water demand which can be met by the water in which they are suspended or by water-containing solid substrates. The actual quantity of water is not as important as its availability in the substrate or medium. A measure of this is the water activity a_w, which is the ratio of the vapor pressure of an aqueous solution to the vapor pressure of the gas dissolved in water. The water activity of pure water is $a_w = 1.0$. The water requirement of bacteria is approximately $a_w = 0.91$, of molds $a_w = 0.80$, and of osmophilic yeasts $a_w = 0.60$ [629].

Nutrient Demand. The approximate composition of a bacterial cell on a dry basis is 50 % carbon, 14 % nitrogen, 2 – 6 % phosphorus, and 1 % sulfur and other elements.

Carbon, nitrogen, and phosphorus are essential for cell growth and producing energy. As a rule, a well-balanced nutrient contains these elements in the approximate ratios (C : N : P) 100 : 5 : 1 (bioscrubbers) or 200 : 10 : 1 (biofilters).

Temperature. Three temperature ranges, in which different types of microorganisms are active, are of interest for biological waste-gas purification processes:

Psychrophilic	10 – 20 °C
Mesophilic	20 – 37 °C
Thermophilic	50 – 65 °C

The activity of the microorganisms increases with temperature, but the solubility of gaseous substances in water decreases. It is important for the reliable operation of a biological waste-gas purification plant to keep its temperature within the appropriate range as consistently as possible to prevent depressions due to population changes. In practice, most installations are operated in the mesophilic range.

The temperature range 37 – 50 °C should be avoided if possible, as a continuous fluctuation between mesophilic and thermophilic microorganisms can occur, reducing the efficiency of the installation.

pH Value. The hydrogen ion concentration in the medium affects the growth and metabolism of the microorganisms. Whereas most heterotrophic bacteria prefer the neutral range, fungi prefer the acid range. The growth and metabolism of microorganisms also cause changes in the pH of the medium. Such changes can be prevented by controlled additions of H_2SO_4 and NaOH (buffering), or by operating multistage equipment at various pH ranges.

7.5.2.2. *Physicochemical Conditions*

Since microorganisms can exist only in or on moist media, they can only metabolize the components of the gas to be treated if these are absorbed in the liquid phase.

Biological waste-gas purification is a biochemical absorption, the result of which is not exclusively determined by the physical solution equilibrium because of the reactive conversion of the dissolved gas [630]. Henry's solubility coefficient plays an important role, and is affected by the temperature and pH of the washing water [631].

As the component dissolved in the wash liquid are biologically degraded by the microorganisms present in a suspended state or fixed in the biofilm, thermodynamic equilibrium cannot be established. The resulting fall in concentration influences diffusion and accelerates absorption. This process depends mainly on the biological reaction rate.

However, with increasing biological activity, the absorption of pollutants depends less and less on the reaction rate and increasingly on the diffusion rate [632].

There are thus two areas in which the absorption process and hence the effectiveness of biological waste-gas purification processes can be influenced:

1. Diffusion
   For a constant concentration in the waste gas, the concentration difference can be increased by increasing the water supply or by additional biological purification of the wash water.
   The solubility can be increased by solubilizing agents (e.g., high-boiling oils) [633].
   The specific exchange surface (phase boundary) in the absorber must be as large as possible.
2. Kinetics
   The reaction conditions (temperature and pH) must be optimized.
   The residence time can be increased by additional aeration stages.
   The biological activity (cell concentration) can be influenced by adding nutrients at appropriate times.

As the microorganisms in a biofilter settle on the moist filter material, two types of transfer occur: adsorption on a solid substance (van der Waals forces) and biochemical absorption. The ratio of the two types of sorption in the filter bed depends on the moisture content of the materials. In purely dry zones only adsorption takes place up to the point of saturation, but no biological degradation can occur.

Biofilters are operated in a moist condition without water circulation, so that the absorption capacity and hence the efficiency of the equipment depends on a homogeneous and uniform flow through the filter bed. The flow behavior of the waste gas through the filter bed is thus determined by the void volume, the gas volume, and the associated relative pressures. The void volume of the material should be distributed uniformly over the filter cross section to ensure uniform flow rates and residence times at all points [634], [635].

Other important factors are the water retention properties of the filter material which determine the water content during operation. With increasing water content, the free void volume in the filter bed decreases and the gas flow rate and the pressure drop increase. The residence time and efficiency of the biofilter therefore both decrease.

7.5.3. ***Biofilters [636]***

Designs. The classical biofilter is the flat filter (see Fig. 95). The conditioned crude gas is compressed in a chamber under a tray provided with holes or slits. The distance between the bottom of the pressure chamber and the grid above should be at least 0.7 m to ensure uniform distribution of the gas flow. The air then flows through the filter bed whose height depends on the material chosen, and should be at least 1 m in a settled state. Flat filters are used where enough floor space is available, and where there are large flow rates with relatively small concentrations of pollutant gas or odoriferous material (e.g., slaughterhouses, composting plants, sewage works). If floor space is restricted, multistage filters of equal area can be stacked one above the other. These can be operated either in parallel or, with multistage operation, in series. In highly loaded waste gases with a low flow rate, e.g., from pharmaceutical and chemical plants especially paint manufacture and processing and in printing works, open or closed container plants (compact plants) can be used.

Figure 95. Schematic of a flat biofilter

a) Filter material; b) Slotted floor; c) Bottom seal

Design Parameters. Because biofilter plants are used to treat complex (odoriferous) gas mixtures, it is seldom possible to perform theoretical calculations. Plant design usually involves comparison with other plants and/or the results of pilot plant experiments. The most important design criterion is the volumetric filter loading, i.e., the amount of waste gas in m^3/h that can be passed through each m^3 of filter material while maintaining a given efficiency.

The bed volume determines the residence time of the waste gases in the filter bed, and depends on the structure and type of filter material. The following materials are used at present:

1. Composted garbage (20 – 40 mm) is sieved out of composted plants and organic domestic waste. This material is biologically highly active, but gives problems with flow obstruction by settled material and uncontrolled gas breakthrough. It is therefore mainly used in combination with inert material (clay, Styropor, and activated carbon) in compact equipment. The bed height is 1.0 m.
2. Coarse material (40 mm, 80 mm, 120 mm) sieved from composted plant material with a bed height of 1.0 – 1.5 m (depending on the humus fraction). The material is biologically very active, but has to be sieved annually.
3. Mixtures of brushwood/fibrous peat, brushwood/coconut fiber, or brushwood/heather are very suitable for flat filters, but can be difficult to procure. The bed height is 1.0 m.
4. Bark mulch from spruce and fir can be used if the material is homogeneously shredded to 50 – 150 mm. The bed height is ca. 1.2 m. Pine bark is unsuitable because it is friable, swells with moisture, and hence obstructs the flow.
5. Cracked root wood pieces, 60 – 180 mm long, can be used if the bed height is at least 1.5 – 1.8 m and is provided with a covering layer of ca. 0.2 m bark mulch for pressure equalization and protection from rain.

The function of a biofilter can be optimized by ensuring that the material has the following properties [637]:

1. Uniform structure (uniform flow and low pressure drop)
2. Adequate void volume (low pressure drop, low specific filter resistance, low energy consumption, good drainage and oxygen supply)
3. High portion of organic material (good additional supply of nutrients, long service life of the filter)
4. Large surface of the carrier material (large specific surface area for occupation by microorganisms)
5. No extreme pH fluctuations in the filter material (good buffer for variations in the waste gas)
6. Good water retention properties (constant moisture)
7. Low rate of decay (long service life, long maintenance intervals)
8. Low odor (low dispersion range of the odor, no unpleasant odor quality)

The balance of these properties is an important condition for optimum functioning of the filter.

The density of the filter material in the wet state is ≤1 t/m^3, depending on the type of material and its condition.

Design Details. Biological methods have only limited ability to smooth out peaks in the concentration of impurities in the waste gas. It is therefore preferable to operate the equipment continuously or to add buffers such as activated coke, to the system.

Biofilter materials become clogged by dust and fats from the waste gas. Also, certain operating ranges of temperature and moisture must be maintained. The crude gas must therefore be conditioned upstream of the biofilter (see Fig. 96). To prevent breakthrough of crude gas at the edge of the filter, a grid floor covering should be provided, extending to 1.0 – 1.5 m from the edge. At a bed height of ≥1.5 m, another edge screen 0.5 m wide should be added.

Figure 96. Preconditioning for a biofilter

a) Fan; b) Dust separator; c) Temperature controller; d) Scrubber; e) Filter bed

On concrete surfaces where biologically active material is present under pressure, e.g., on prefabricated slatted floors used in agricultural equipment, biological corrosion can take place. These surfaces should be sealed with liquid resin. Corrosion has so far not been found on the concrete walls or other equipment under the grid.

It is not necessary to provide a cover on flat filters, but a duct under the grid is required for seepage water. This water can be supplied to the scrubber for humidifying the crude gas, or can be sprinkled on the filter. Thus, the biofilter operates without producing waste water.

Maintenance and Repair. The filter bed must be kept free of plant growth, and must be regularly checked for settled material and gas breakthroughs. Fine filter materials has to be loosened and sieved at least once a year. In the case of cracked root packings, it is sufficient to loosen the top layer. As degradation of organic substances takes place in the filter material, an addition of ca. 5 – 10 % of the material volume must be made annually. Complete replacement of the material

is only necessary if the degradation process has proceeded to such an extent that the required air flow rate can no longer be achieved. To enable replacement or sieving of the filter material, the biofilter equipment has to be designed and constructed such that the grid is accessible for vehicles (wheel loader) or the filter can be maintained with a mobile gripper. The biofilter should be divided into several segments so that the entire production need not be shut down for maintenance work.

Process Monitoring. Biological waste-gas purification processes require a start-up period of 4 – 8 weeks, depending on the composition and concentration of the waste gas. It is only necessary to inoculate the filter if it is filled with an inert material. If waste-gas compositions match those of the associated sewage plants, sewage sludge can be sprinkled on the biofilter to increase its efficiency and to reactivate the biological activity rapidly after a long shutdown. The water content and pH of the material in the filter must be continuously monitored and controlled.

Additions of nutrients are only necessary if there is a deficiency in carbon, nitrogen, and phosphorus in both the waste gas and the filter material. Such a deficiency can occur after a long shutdown period or production changeovers.

Another important operating parameter is the continuous monitoring of the pressure drop in the filter bed. This indicates whether the filter bed has settled or whether surface densification (e.g., due to heavy rain) has occurred. Permeability properties are tested with smoke cartridges or fog generators.

7.5.4. *Bioscrubbers [630]*

Designs. Biological gas scrubbing can be carried out in bioscrubbers containing suspended microorganisms (see Fig. 97). They include an absorber in which the constituents of the waste gas are dissolved in the scrubbing liquid. This is collected in the absorber, and fed to an aerated activating tank. The regenerated scrubbing liquid is then recirculated to the absorber. The degradation efficiency depends on the active sludge mass formed from the microorganisms suspended in the scrubbing liquid and the dissolved pollutants. The limiting factor for this process is the distribution coefficient: for sparingly water-soluble substances in the waste gas extremely large amounts of water – sludge mixture have to be available and kept in circulation. For economic operation, the distribution coefficient should be higher than the limit value of 0.0005 g/m^3 gas to 1 g/m^3 liquid. The addition of a high-boiling oil (e.g., a methylsilicone fluid) as a 10 – 30 % dispersion to the water – sludge mixture can increase the absorption rate by a factor of 100 – 1000 [633, 640, 641].

Figure 97. Bioscrubber with suspended microorganisms

a) Absorber; b) Activated sludge circulation; c) Activating tank

In a trickling-bed reactor, absorption and biological degradation take place in the same part of the equipment (see Fig. 98). The scrubbing liquid is circulated over an inert packing material and collected in a pump sump. A biological film forms on this material, which can consist of loose filling material or a structured packing. The oxygen needed for biological degradation and the constituents of the waste gas to be degraded are absorbed by the water phase and transported to the biofilm where the reaction takes place. The degradation capacity depends on the specific surface of the packing, i.e., of the biofilm, and the residence time in the trickle bed.

Figure 98. Trickling-bed reactor with fixed microorganisms

a) Demister; b) Nozzles; c) Packing material with biological coating; d) Pump sump; e) Water circulation

Because mass transfer from the gas to the liquid phase takes place at the same time as the reaction on the biofilm of the absorber, the trickling-bed reactor can be used if the distribution coefficient (g/m^3 gas to g/m^3 liquid) of the components to be degraded is higher than 0.0005 [637].

Design Parameters. There are more design criteria to be considered with bioscrubbers and trickling-bed reactors than with biofilters. A correctly dimensioned and operated biofilter has a large buffering capacity which a bioscrubber cannot have, as the latter has to give the same purification efficiency with only a fraction of the biologically active volume. Whereas in biofilters only small parts can become overloaded or sour and respond to toxic substances, disturbances in bioscrubbers have an immediate effect on the entire biosystem.

Therefore, it has to be determined at a preplanning stage whether certain components of the waste gas that are harmful to the microorganisms or can clog the packing need to be removed by dedusters or prescrubbers before they reach the bioscrubbers. It must also be decided whether the composition of the waste gas makes a two-stage operation (acid/neutral) necessary.

The reaction products and cell mass become concentrated in the circulating scrubbing liquid. Part of the scrubbing liquid therefore has to be removed at regular intervals and replaced by fresh water or solution. Any solubilizing agents used have

to be separated before the spent liquid is disposed of.

Thus, bioscrubbers are waste-gas purification devices producing wastewater (according to the German Water Management Act they are not wastewater purification devices). As a rule, the mixture of water and suspended material which is continuously removed from the installation does not contain heavy metals and other hazardous substances, and can therefore be disposed of in domestic sewage plants without problems. Ranges of characteristic parameters for bioscrubbers can be found in [630, 633, 638, 639].

If the necessary design parameters are unknown because the mixture of substances to be treated cannot be precisely determined, as in the case of emissions of odorous substances, pilot plant investigations have to be carried out. If the waste-gas load cannot be reproduced, reference substances may be used to test the purifying efficiency of the pilot plant.

Design Details. Materials that come into contact with intensive biological activity have to be protected from (biological) corrosion. Metals inside a scrubber, including stainless steels and seawater-resistant aluminum, have to be coated with plastic.

Packings in absorbers and trickling filters have to be designed and constructed such that a biofilm can form while a low pressure drop is guaranteed and the packing does not become clogged with activated sludge. A good impingement force of water will prevent clogging and flow obstructions, and there large inspection openings are necessary to enable an easy addition and removal of the packing material.

The scrubbing liquid distribution system above the packing material needs to be designed to operate without blockages. The water circulation pumps have to be suitable for transporting activated sludge, and need to run slowly so that the sludge flocks formed in the activating tank are not broken down. Displacement or slow-running plunger pumps are therefore recommended.

Process Monitoring. All the parameters relevant to operation of the process, such as temperature, pH of the scrubbing liquid, pressures in the scrubbers, oxygen and nutrient concentrations, and characteristics of the spent scrubbing liquid have to be determined continuously or at regular intervals for process control. Maintenance at regular intervals is therefore unnecessary, as the packed bed need only be cleaned when the pressure drop indicates flow obstruction. When biological scrubbing equipment is in the initial start-up phase, e.g., after inoculation with activated sludge from an associated sewage treatment plant, natural selection of the microorganisms (adaptation) takes place for 4 – 6 weeks. Significant changes or fluctuations in the crude gas composition may require re-adaptation, which can also take several weeks.

During plant shutdowns when no pollutants are added via the waste gas, nutrients have to be added to the scrubbing liquid by metering devices. The biological oxygen demand must be continuously supplied by aeration of the activating tank or by passing indoor air through the absorber.

Process Optimization. The purification efficiencies of biological plants can be improved by connecting a trickling-bed reactor with a biofilter to form a two-stage process. The first stage acts as a neutralizer, reacting with acid or basic components of the waste gas. The biofilter is then used without special control techniques to reduce the residual pollution.

Further developments have led to the biosorber principle [642], a biofilter and a bioscrubber combined in a single unit. This consists of a packing of inert material on the surface of which nutrient media specially suitable for the application are grown.

In the biomembrane principle [643], strongly hydrophobic waste gas components diffuse under pressure through a silicone tube located in a mixture of activated sludge, water, and, if necessary, solubilizing agent. The tube is coated on the outside by a biofilm, so that the biological reaction takes place in the biofilm and the waste gas components need not be dissolved in a liquid. Waste gas components that are not picked up by the biofilm can then be treated in the activating tanks.

Measurement and Assessment. Determination of the gaseous components of a waste gas before and after biological purification is carried out by a wide range of methods, including gas chromatography, and spectrometry. To determine odoriferous substances, olfactometry is used for measuring emissions [644], and field inspection with panelists is used for ambient air pollution [645]. The following criteria should be taken into account:

1. Determination of the odor concentration in the waste gas is by itself not a criterion for odor nuisance. The odor intensity [646] and the position on the hedonic scale [647] also need to be determined.
2. The odor of the crude gas is changed by the biological treatment. This “biological smell”, which is undetectable a few meters away from the equipment, also has an odor concentration, so that the calculated efficiency gives a false impression of the purification performance of the equipment.
3. Biofilter material, e.g., composted domestic waste, can have its own specific odor.

Assessment of the ability of a biological process to remove odor emissions therefore has to be carried out in accordance with the VDI Guidelines [630], [636], which state that the aim of the purification process is achieved when the characteristic odor of the crude gas is undetectable after purification in the biofilter or bioscrubber.

7.6. Flue-Gas Purification in the Incineration of Hazardous Waste

In the incineration of hazardous waste, the methods and equipment described in Sections Separation of Solid and Liquid Particles from Gases , Waste-Gas Purification by Thermalor Catalytic Reactions, Absorption, Adsorption, Biological Processes are used together with additional technical and operational procedures to enable high standards of environmental protection to be met. As a result of their composition, condition, or quantity, such materials can endanger health, the atmosphere, or water supplies, or they can constitute an explosive hazard. Typical substances include:

1. Solvent mixtures
2. Industrial sludges
3. Paint residues
4. Plastic waste
5. Inorganic waste (salts)
6. Halogenated hydrocarbons
7. Petrochemical residues
8. Halogenated acids/alkalis
9. Pharmaceutical waste
10. Acid sludge
11. Waste oil
12. Pesticides
13. Herbicides

If hazardous wastes cannot be treated or reused and direct dumping is impossible, they must be incinerated to destroy their organic constituents and produce inert combustion products that can be reused or safely dumped. By far the largest quantities of hazardous waste are incinerated in rotary furnaces. This enables the incineration of solids, liquids, and pastes and the thermal treatment of substances that produce molten slags during the incineration process. Solids and pastes are added by crane loaders and liquids through burners and lances, or barrels are charged to the furnace intact.

A simplified flow diagram of a complete plant is shown in Figure 99 and a section through an actual plant in Figure 100.

Figure 99. A) Simplified flow diagram of a hazardous-waste incineration plant

B) Flow diagram of a rotary furnace

Figure 100. Hazardous-waste incineration plant

With kind permission of the L. & C. Steinmüller GmbH, Gummersbach, Federal Republic of Germany

In the incineration process, the elemental constituents of the waste are retained, but their chemical and physical forms are changed. To prevent unacceptable contamination of the environment by hazardous substances, either by their entry into the atmosphere or as solids, the operation of hazardous-waste incineration plants must include comprehensive measures to reduce emissions.

Typical concentrations of pollutants in crude gas produced by “publicly” operated incineration plants used to treat waste from trade, business, and industry are:

Dust	1000 – 10 000 mg/m^3
Inorganic chlorine compounds (as HCl)	3000 – 10 000 mg/m^3
Inorganic fluorine compounds (as HF)	50 – 550 mg/m^3
Sulfur compounds (SO_2 + SO_3)	1500 – 5000 mg/m^3
Nitrogen oxides (as NO_2)	100 – 300 mg/m^3
Water vapor (H_2O)	6 – 20 vol %

In plants operated by the chemical industry for the incineration of production residues with high contents of reactive substances, a much wider range of concentrations can occur in the waste gas. Table 24 lists the legally required emission limit values for existing and newly constructed plants in Germany. The emission limit values in an EC Guideline proposed in 1993 and given legal force in the 1994 plan are also given. These are to be incorporated in National Law within two years.

Table 24. Waste incineration emission limit values simplified synopsis of EG Guideline/17th BImSchV, Germany (limit values in mg/m^3 based on STP and 11 % O_2)

Component	EG Guideline 17. BImSchV

Carbon monoxide		
Daily mean value	50	50
Hourly mean value		100
90 % of all measurements (peak concentration) in 24 h		150
95 % of all 10 min mean values in 24 h	150	
Daily mean values (DMV)		
Total dust	10	10
Organic substances (total-C)	10	10
Hydrogen chloride	10	10
Hydrogen fluoride	1	1
Sulfur dioxide	50	50
Nitrogen dioxide	(none)	200
Half-hour mean values (HMV)		
Total dust	30	30
Organic substances (total-C)	20	20
Hydrogen chloride	60	60
Hydrogen fluoride	4	4
Sulfur dioxide	200	200
Nitrogen dioxide	(none)	400

The emission limits for conventional air pollutants have been reduced considerably, and a new limit value for the emission of polychlorinated dibenzodioxins and dibenzofurans (PCDD/PCDF) has been introduced. Whereas emissions of conventional atmospheric pollutants are essentially a function of the type, amount, and composition of the waste materials incinerated, dioxins and furans and other organic hydrocarbons are formed by complex decomposition and side reactions in the combustion and cooling processes.

According to current knowledge, most of the dioxins and furans found in the flue gas are formed from unchlorinated organic material in the presence of a chlorine source. In the temperature range 450 – 250 °C, catalytic formation of chlorine from metal chlorides in the presence of oxygen is the essential initiation reaction. The mechanism of formation assumes the presence of chlorine and oxygen, and this is unavoidable in the flue gases produced by incineration of hazardous waste. Dioxins are formed in a solid state reaction, and are mainly bonded to particles.

The primary emission control measures are meticulous planning of the incineration process and control of the firing process. The incineration plan determines how the waste materials are metered and added. If possible, they are size reduced and mixed to ensure that the furnace feed has consistent properties, including calorific value, content of components such as halogens, sulfur, nitrogen, heavy metals and organic compounds, and other properties relevant to the incineration process such as ease of ignition and burning rate. Drums to be added intact to the incinerator for reasons of operational safety must be of a size and energy content suitable for the firing equipment. Owing to the heterogeneous nature of the fuel, the usual systems for controlling the combustion air are unsuitable. The amount of combustion air is often fixed and the waste material is added in a controlled manner to give the required temperature, controlling the CO content at the same time. Emission control measures in the incineration process affect almost exclusively the carbon monoxide level and the total content of organic compounds.

The special characteristics of the rotary furnace, such as the frequent change of fuel for the burners and sludge lances and feeding of drums lead to large, brief fluctuations in the flue gas composition. High air pollutant concentrations that change according to the feed and the combustion conditions must be dealt with by secondary emission control measures. For a flue-gas cleaning system for a modern hazardous-waste incineration plant, not only must the capacity to remove pollutants be high, but also the following requirements must be met:

1. The process must be designed so that no wastewater is produced
2. Residues from the various processes used in waste-gas purification must be reused as far as economically possible
3. Residues that cannot be reused must be safely dumped

The costs of dumping depend on the nature of the waste material. For example, the disposal of residues containing heavy metals, dioxins, and soluble salts in an underground dump is approximately five times as expensive as disposal in an open hazardous-waste dump supervised in accordance with modern technical regulations. Therefore, on cost grounds, every operator endeavors to concentrate potentially environmentally hazardous substances as far as possible, so that only small amounts of residues will need expensive treatment. Finally, flue-gas purification must function with a high degree of safety and at low operating cost.

Flue-gas purification equipment for hazardous-waste incineration plants usually incorporates a dry dedusting stage and several wet scrubbing stages. A design of such elements including spray tower scrubbers is shown in Figure 101. The combustion exhaust gases are cooled in a steam-generating heat exchanger to ca. 250 °C. The design concept requires

1. Preliminary dedusting of the waste gases by a double-field electrostatic filter
2. An initial scrubbing stage to cool the combustion gas to the cooling limit temperature (quench), with removal of HF, HCl, and heavy metals
3. A second scrubbing stage to remove SO_2, producing the required waste-gas purity
4. Wastewater treatment including gypsum production and external evaporation of the $CaCl_2$ solution produced

Figure 101. Dedusting and wet scrubbing stages as elements of flue-gas purification system

The first scrubbing stage, also termed the prescrubber, is operated at pH <2 to remove HCl, HF, and heavy metals. At this pH, the chloride content of the wastewater can be high, which is indispensible or advantageous for the external evaporation step. In the first scrubbing stage, only a limited amount of SO_2 is removed. The sulfite formed is oxidized to sulfate by aeration of the sump. The second scrubbing stage, also termed the main scrubber, predominantly removes SO_2. In the spray tower, the suspension used for the scrubbing is introduced via nozzles at different three levels. The droplet content on the pure gas side should be as low as possible. The droplets are removed by an internal and an external demister. Sulfur dioxide scrubbers are operated at pH 6.5 – 7; the absorption medium is milk of lime. The salts (mainly gypsum) formed by reaction with SO_2 are removed in the wastewater treatment stage. To improve the ease of water removal from the insoluble salts and to ensure high purity of the separated sulfate (>99 % $CaSO_4$ in the solid), the sulfite formed during the absorption is oxidized to sulfate by passing air into the sump of the scrubber. Fine crystals must be avoided as far as possible in the sulfate crystallization. Therefore, a solids content of ca. 8 % is maintained in the wash liquor suspension to ensure that enough seed crystals are produced during the crystallization and spontaneous nucleation is avoided. The $CaSO_4$ formed is removed from the scrubber overflow by a thickener and band filter. The clear fraction is returned to the scrubbers, and a small percentage is taken directly to wastewater treatment.

Special technical measures must be taken to deal with fluctuations in the concentration of the waste-gas constituents. By using rapidly responding control systems and by directly feeding the absorption medium into the scrubber inlet pipes, an adequate quantity of absorption medium is provided at all operating points. The rate of addition of the suspension is controlled in accordance with the concentrations measured in the crude gas after the electrostatic filter. Both scrubbers include normal methods for measuring and controlling pH, density of the suspension, and flow rates by cascade controllers. Temporary supersaturation in the first scrubbing stage can lead to incrustation and scaling. This is prevented by spraying the top of the scrubber with fresh water. This mechanical and chemical rinsing also provides the water required for the process. Hydrogen chloride peaks not eliminated in the prescrubber are reduced to permissible levels in the main scrubber. Any significant chloride loading in the main washer is undesirable because it has an unfavorable effect on the equilibrium conditions for SO_2 removal. Therefore, an external demister is included between the prescrubber and the main scrubber. As well as the cascade control system in the main scrubber, additional equipment is necessary in the liquid circulation system to maintain the liquid balance and achieve the necessary oxidation and crystallization of the insoluble solids simultaneously with the removal of SO_2.

The spray tower scrubber can be used as an example of the problems to be solved when transferring a process technology to full industrial scale. In other full scale plants, spray scrubbers, rotary scrubbers, venturi scrubbers, or packed tower scrubbers are used. Sodium hydroxide solution can be used as an alternative to a milk of lime as absorption medium. Sodium salts are soluble in water, which avoids the danger of incrustations in pipework and equipment. Instead of the electrostatic filter, a cloth filter can also be used. The choice depends on the material to be incinerated. Cloth filters, which are usually operated at ≤ 200 °C, are unsuitable, if there is a danger of clogging by fine dust produced in the incineration process, or if the dust is hygroscopic and forms coatings on the filter that cannot be removed. Electrostatic filters are unsuitable if the dust cannot be electrostatically precipitated, if the electrical resistance of the dust layer is too high, or if the dust has such a low density (e.g., in the incineration of chlorosilane) that it is not removed on trapping the electrostatic elements. Therefore, in some areas of the chemical industry dry removal of dust is infeasible. For wet-dust removal, single-stage or multistage venturi or rotary scrubbers can be used (see Section Wet Scrubbers). These operate on the principle of contacting the dust-laden waste gas with a relatively finely dispersed liquid. The dust particles come into contact with the liquid droplets, are wetted, and are collected along with the liquid. The dust must therefore be wettable.

The liquid from the scrubbers goes to a water-treatment stage which includes the precipitation of heavy metals, flocculation, and solids separation. The heavy metal sludge also contains dioxins bound to the dust collected by the scrubbers. The clarified liquid is evaporated externally (if the dry product can be sold) or internally by a spray dryer that forms part of the main waste-gas stream. Internal evaporation produces a relatively large amount of a dust – salt mixture containing dioxin and heavy metals. This residue is usually disposed of by underground dumping.

In the process described above, mercury is removed in the first, acid scrubbing stage. The residual concentration in the purified gas depends on the vapor pressure of mercury. If mercury concentration peaks occur or if mercury is present in the scrubber in metallic form (e.g., caused by dissolved sulfur dioxide), this can lead to the breakthrough of mercury, which can then exceed emission limit values. This system also does not include any process to limit the emission of nitrogen oxides. If large amounts of aerosols are present, there is an increase in the dust content and hence also in the dioxin content of the purified gas.

Thus, the process technology for waste-gas purification must be improved for new plants. There are many proposals based on laboratory or pilot plants. Emissions of nitrogen oxides can be reduced by the selective catalytic reduction (SCR) process as used in power station technology. Only the low-dust variant is relevant. The waste gas must be reheated to ca. 250 – 300 °C before it enters the catalyst, by heat transfer from the hot to the cold waste gas or by heating with burners. Experiments have shown that when catalysts are used to reduce emissions of nitrogen oxides, organic trace substances such as dioxin can also be catalytically oxidized. Reaction efficiencies (removal efficiencies) of ca. 90 % for PCDD and PCDF have been found in semitechnical experiments. The oxidation catalyst would then perform two of the additional emission-control tasks required. A particular advantage is that no additional residue is produced in this process.

In many hazardous-waste incineration plants, nitrogen oxide concentrations in the crude gas are < 300 mg/m^3. To achieve the legally required value of 200 mg/m^3, a reduction of 30 % is necessary. This can be achieved either by the selective noncatalytic reduction (SNCR) process in which ammonia or aqueous ammonia solution is added to the waste gas at 850 – 1000 °C. As the reaction does not proceed to completion, ammonium chloride can be formed as an aerosol. Furthermore it can be assumed that some of the ammonia will go into solution in the first scrubbing stage and must then be removed in a stripping operation.

To remove aerosols, a wet electrostatic filter can be used as final purification stage. The purified gas leaving the last scrubbing stage is cooled until droplets form and agglomerate, and the droplets are removed by an electric field. Decreasing the dust content of the purified gas automatically reduces dioxin emissions. If cooling before the wet electrostatic filter gives a temperature of up to 20 °C below the cooling limit temperature, the mercury content is also reduced because of the lower vapor pressure.

Multifunctional separations are achieved by activated carbon filters (see Section Adsorption), which have undergone rapid development. They have been tested in full-scale experiments, and are already used in one hazardous-waste incineration plant in Germany. Activated carbon filters, operated as fixed or moving beds (Fig. 102), adsorb heavy metals and organic trace substances simultaneously. They also adsorb any hydrogen chloride and sulfur dioxide that have passed through the earlier stages. If they are used on the purified-gas side, the consumption of activated carbon is very low. Entrainment reactors can also be used, in which a mixture of activated calcium carbonate with a proportion of activated carbon is blown into the waste gas and then removed on a cloth filter. Using this as the final stage waste-gas purification gives results as good as those obtained with moving or fixed bed activated carbon filters. Examples of analysis figures for the purified gas in full-scale plants are given in Table 25. Technical-grade hydrochloric acid can be produced from the chloride solution generated in the first scrubbing stage. For this, the first scrubbing operation is carried out in three stages, in which dust and heavy metals are removed in the first stage, the required concentration of HCl is obtained in the second stage, and the third stage performs the final purification. The hydrochloric acid is removed and distilled. The distillation process would replace an external evaporation of chlorides, which are generally difficult to market.

Table 25. Comparison of emission limit values according to EC Regulations and 17th BImSchV (Germany) with initial results from a hazardous waste incineration plant with a carbon filter with an activated coal – lime cloth filter. Values are in mg/m^3 at STP based on 11 % O_2

	Emission limit (mean values)		Daily mean values Dec. 91 – Feb. 92
	17. BImSchV		
	Daily	Half-hourly	
Total dust	10	30	<1 [a]

Figure 102. Hearth furnace coke adsorber – shaped activated carbon catalyst (countercurrent flow)

All these processes for additional waste-gas purification and reuse of residues can lead to complex design and process technology (Fig. 103). Plants of this type have not yet been realized. In Germany the first plants of this type will be put into operation in 1996 and 1997.

It was formerly intended that hazardous-waste incineration plants should be designed for the treatment of all types of hazardous waste using all techniques available. These requirements now appear to be changing. It is apparent that the cost of incineration is increasing rapidly, and cheaper methods for disposing of hazardous waste will be sought.

The positive results obtained using the entrainment method and the fact that the SNCR method for removing nitrogen oxides has been very effective have led to a reassessment of the situation. It is likely that in future hazardous waste will be more carefully sorted to match the material to the incineration method used. Wastes that do not require high-quality gas purification will then be treated in the appropriate plants using simpler techniques like dry or semidry absorption methods.

8. Photochemical Degradation

Walter Simmler

8.1. Introduction

In terms of mass and energy turnover, photochemical degradation is one of the largest chemical reactions in nature. It is ultimately an oxidation process involving numerous physicochemical intermediates. It takes place in the troposphere and makes an essential contribution to global recycling because of its mineralizing effects, leading to the formation of carbon dioxide and water. In simple terms, photochemical degradation starts with the formation of reactive species, usually radicals, when the molecules of certain atmospheric trace substances are cleaved by sunlight. These species then react with other, mineralizable trace substances.

These in turn can be of natural and anthropogenic origin: organic and inorganic components of sea spray, exudates from forests, products of biotic transformation processes, agriculture, industrial emissions, etc. [648-650].

The most important single process which brings about natural purification of the atmosphere is the formation of hydroxyl radicals, which oxidize hydrocarbons and their derivatives, e.g.,

$$O_2 + NO_2 \xrightarrow{h\nu} NO + O_3$$

$$O_3 + H_2O \xrightarrow{h\nu} O_2 + 2\,{}^{\bullet}OH$$

$$2\,{}^{\bullet}OH + CO \longrightarrow H_2O + CO_2$$

Here, as in most other cases, it is indirect photochemical degradation that is taking place. Direct photochemical degradation — the absorption of a light quantum followed immediately, or after rearrangement, by oxidation — is comparatively rare and plays only a minor role in natural purification of the atmosphere and in special cases of industrial air purification. The term photochemical degradation is often used in the literature for reasons of simplicity when indirect photochemical degradation is really meant.

The hydroxyl radical is the most important oxidizing agent formed photochemically, although it is present at a concentration of only 0.5×10^6 molecules/cm^{-3}. However, it reacts rapidly and fairly unselectively, is continuously formed, and is involved in the first stage of most oxidative transformations in the troposphere. In contrast the activation energy for direct oxidations by molecular oxygen in the troposphere is so high that measurable effects are not accomplished in reasonable periods of time.

For determining the lifetimes of chemical substances in the environment or of their residence times in individual environmental compartments, atmospheric conditions and processes are of great importance, especially in the case of emissions into the atmosphere of homogeneous gases or substances bound to particles. This also holds for deposition and other immissions from the air. Interactions with energy fluxes in the atmosphere and with atmospheric cycles of trace substances are particularly important [651-656].

The role of the atmosphere has many aspects: air acts as a container, vehicle, reactor, reactant, and filter, these functions sometimes being mutually interdependent. Here, the decisive feature is the characteristic temperature profile with increasing elevation (Fig. 104) [649], [657], [658].

Figure 104. Atmospheric strata with temperature profile

(Origin: Funds of Chemical Industry “Ecological Compartment Air”, 1987)

From ground level, the temperature at first decreases linearly by ca. 6.5 °C/km. This zone, the troposphere, extends to an altitude of ca. 10 km (9 km at the poles, 15 km at the equator). It is formed by rising masses of air heated by the earth's surface and then subsequently cooled. Above the boundary zone (the tropopause), the stratosphere begins, and temperature now increases with altitude as a result of solar radiation; short-wave sunlight is directly absorbed. The absorbing substance is ozone in the lower stratosphere (altitude ca. 25 km) where the O_3 concentration is ca. 10^{12} molecules/cm^3. The ozone concentration decreases rapidly both above and below this zone. The presence of ozone in the lower parts of the troposphere is a result of other formation mechanisms (see Section Reaction Cycles in the Atmosphere).

The inversion of the temperature gradient above the tropopause is essential for maintaining the stability of the stratosphere. It causes the formation of a zone which acts as a barrier layer that prevents rapid ascent of trace gases from the earth's surface into the stratosphere. The vertical diffusion coefficient is at a minimum at this point, and penetration through this layer takes several years.

The composition, i.e., the nature and amount of the principal reactants in the zones of the troposphere close to the earth's surface, determines the processes that lead to degradation (Fig. 105).

Figure 105. Characteristic concentrations (in molecules/cm^3) and volume mixing ratios (= mole fraction) of tropospheric main and selected trace gases

The hatched areas indicate common variabilities

HC = hydrocarbons

Apart from concentration, the various reaction rate constants of the trace substances are decisive (see Section Measurement and Computation of Degradability). The only source of energy is the sun. The energy flux for vertical radiation has a mean value of 1378 W/m^2, corresponding to a total annual energy intake of 1.56×10^{18} kW · h, with the radiation maximum at 480 nm (yellow-green). Of this, ca. 70 % is absorbed at the earth's surface on a cloudless day in Central Europe (Fig. 106).

Figure 106. Percentage energy balance of the earth's surface

(Origin: Funds of Chemical Industry “Ecological Compartment Air”, 1987)

In the lower troposphere the fraction of the radiation absorbed is 17 %. This corresponds to a daily amount comparable to annual global energy consumption by humans today. After subtraction of the dissipated light from the incident light, a proportion remains for tropospheric photochemistry [659]. Figure 107 shows the spectral distribution of sunlight and the limiting wavelengths for important photolysis reactions.

Figure 107. Spectral distribution of sunlight and wavelength limits for some important photolytic reactions

a) Incident sunlight reaching the outer atmosphere; b) Incident sunlight reaching the earth's surface

Hatched area: portion of light absorbed in higher atmospheric strata

The formation of photooxidants and their reaction with pollutants entering the troposphere primarily depends on the photodissociation of O_2 and O_3. The fundamental reactions were formulated as early as 1930, albeit for the stratosphere [660].

8.2. Natural and Anthropogenic Emissions

Photoinduced degradation of emissions that enter the atmosphere from the earth's surface is achieved by physical processes, particularly those occurring in the zones of the troposphere near ground level, and by trace gases that are already present there, especially carbon monoxide, methane, and nitrogen oxides. Via formation of photooxidants, they determine the rate of degradation of other trace substances emitted into the atmosphere. Several billion tonnes of such substances are emitted from the earth's surface annually. They are chemically transformed in the troposphere, mainly by mineralization to form oxidation products, and return as such to the earth's surface [661], [662].

The concentration of a trace substance is determined by its rates of emission and degradation. The most important of such substances (Table 26), originating from various sources, are measured and calculated [649, 651, 663-669].

Table 26. Global annual emissions*

	Emission rate, 10^9 kg/a	Main sources, 10^9 kg/a	
Carbon dioxide	830 000	respiration, biological degradation	370 000 – 520 000
	(700 000 – 1 000 000)	oceans	300 000 – 450 000
		combustion of fossil fuels and forest clearance	20 000 – 30 000
Carbon monoxide	3400	combustion of biomass	400 – 1600
	(1700 – 5800)	combustion of fossil fuels	500 – 800
		oxidation of hydrocarbons in the atmosphere	800 – 2200
Hydrocarbons except CH_4 (calculated as C)	1000	trees (terpenes, isoprenes)	600 – 1300
	(640 – 1400)	motor vehicles	30 – 50
		solvents	10 – 20
Methane	500	swamps and geothermal activity	100 – 300
	(350 – 1600)	rice paddies	50 – 300
		animal husbandry (ruminants)	100 – 200
		termites	100 – 150

Sulfur compounds (calculated as SO_2)	400	combustion of coal and mineral oil	160 – 240
	(290 – 500)	oxidation of sulfur compounds from oceans, swamps, etc.	80 – 200
		volcanoes	10 – 20
Nitrogen oxides excluding N_2O (calculated as NO_2)	160	combustion of fossil fuels	40 – 80
	(70 – 320)	combustion of biomass	10 – 80
		lightning	7 – 70
		atmospheric oxidation of ammonia	3 – 30
Ammonia	100	biological degradation, soil	up to 1200
	(30 – 1200)	animals	20 – 30
		wastewater treatment	10
Dinitrogen oxide	50	soil	up to 600
	(10 – 600)	oceans	6 – 15
Hydrogen	50	hydrocarbon oxidation	20 – 50
	(40 – 130)	industry and traffic	10 – 60

* This table lists the probable total annual quantities of emissions of various substances. The spread of values quoted in the literature is given in parentheses. Because the estimates of the main emission sources show such wide divergence, only the ranges of these estimates is shown.

In many countries of the world (Table 27), certain emissions are continuously measured [663]: CO_2, CH_4, and N_2O because of the greenhouse effect, and CFCs because of their effect on the ozone layer.

Table 27. Main emissions by countries (10^3 t/a)

	CO_2			CH_4	CFCs	N_2O
	From energy use	**From industrial processes**	**Total**			
Canada	435 400	25 700	461 100	3 700	14	92
United States	5 035 000	31 950	5 066 950	29 000	90	428
Japan	1 078 900	46 600	1 125 500	1 338	111	47
Germany	956 900	25 000	981 900	6 060	15	220
Italy	418 500	92 078	510 578	3 646	25	42

Sweden	56 300	3 250	59 550	490	2	11
United Kingdom	608 400	5 981	614 381	4 844	31	109
OECD	10 438 660	372 880	10 811 540	63 840	350	
World	21 613 300	733 850	22 347 150	274 930	480	

By 1978, over 1300 trace substances had been identified in the atmosphere [667]. Substances of low vapor pressure enter the atmosphere bound to dusts [653], [670-672], and take part in photochemical degradation like other aerosols (see Sections Natural and Anthropogenic Emissions and Lifetimes of Adsorbates Aerosols). Horizontal transport processes occur in this way, and often removal of transformation products from the troposphere by precipitation. Smog, which can have a variety of compositions, modes of formation, and reaction paths is also included here, especially in connection with reaction cycles, atmospheric lifetime, and quality assessment.

So-called London smog differs from Los Angeles smog, also referred to as photosmog. London smog was formed when the smoke from domestic fires typical of the technological state of the art in the early 1900s combined with fog. Owing to the use of sulfur-containing fuels, the smog was acidic, and catalytic oxidation by heavy metal containing dusts converted sulfur dioxide to the trioxide. This type of smog occurred particularly under conditions of atmospheric inversion typical of the winter. Today, improved combustion technology and low-sulfur fuels have led to its virtual disappearance worldwide.

Los Angeles smog is also formed in inversion conditions but is caused by intense solar radiation acting on emissions from motor vehicles. Volatile organic compounds (VOCs) behave similarly, with the exception of methane. Systems of this general type are referred to as photosmog [649], [673]. It consists of photooxidants — products of the oxidation of VOCs by nitrogen oxides. Generally, these are organic nitrates and peroxo compounds such as hydrogen peroxide, methyl

hydroperoxide, peroxyacetic acid, peroxynitric acid, and peroxyacetyl nitrate. The most important component of photosmog is ozone, which far exceeds all other compounds in concentration [674]. The formation and reactivity of photosmog depend very much on the time of day, and follow complex mechanisms (see Section The Stratosphere).

Information about the earlier condition and behavior of the atmosphere is provided by investigations of sample cores from boreholes drilled in the ice of polar regions, especially Greenland and the Antarctic, and also from cores obtained from the seabed. Contained in the occluded gas bubbles are trace substances from earlier times, including materials deposited as solid particles from the atmosphere, e.g., from volcanic eruptions or meteorite impacts. The mightiest continental ice shield is found in the South Polar regions, with a thickness profile corresponding to a time span of over 100 000 a. The composition of the troposphere can thus be traced back over this time period. The carbon-containing compounds, especially methane, carbon monoxide, and carbon dioxide, are the most meaningful as they are partly of anthropogenic origin and participate in the most important tropospheric reaction cycles. They have been thoroughly, and in some cases continually investigated, as shown by the example of emission data for methane:

Sources (10^{12} g/a)

1. *Fossil deposits*
   As 18 – 24 % of the methane does not contain any radioactive ^{14}C, the amount from fossil deposits is (100 ± 20) × 10^{12} g/a:

from coal mines	25 ± 5
from methane hydrates	~5
from losses of natural gas	70 ± 15

   Thus, 6 – 9 % of natural gas production is lost as CH_4 emissions
2. *Biogenic sources*

Ruminants	~80
Dumps	50 ± 20
Ocean and termites	~30
Wet regions and rice paddies	215 ± 50
Combustion of biomass	30 ± 15
Total sources	505 ± 105

Sinks

OH oxidation	420 ± 80
Uptake by the soil	30 ± 15
Stratospheric degradation by Cl and O (^1D)	10 ± 5
Subtotal	460 ± 100
Annual increase	45 ± 5

The main sources of methane are in the undeveloped countries [675], and the main sources of nitrogen oxides in the industrialized countries [676].

Emissions of NO_x (10^6 t/a, calculated as NO_2) can be summarized as follows:

Ground sources	124
Combustion of fossil fuels	69
Emissions from the soil	18
Combustion of biomass	37
Atmospheric sources	30
NH_3 oxidation	10.2
Lightning	16.4
Aircraft exhaust gases	1.0
NO_x from the stratosphere	2.0

Total	154 ± 76

Emissions in the form of aerosols make a large contribution to the input to the troposphere. In total, 1 – 2 × 10^6 t are added annually, of which 10 % is of anthropogenic origin [653] (Fig. 108). The inorganic material in aerosols alone is considered to have a total surface area of 2 – 10 times that of the earth [677] and a residence time of 1 – 14 d [678].

Figure 108. Source strength of the inorganic fraction of the atmospheric aerosol

The anthropogenic portion dominating in industrialized countries is split into various contributions in the right-hand diagram. The hatched areas denote light-absorbing aerosol materials with semiconductor properties.

Trends are of particular interest, especially those that influence anthropogenic activities or are initiated or directly caused by them. Of primary concern today is the increase in CO_2 emissions. The carbon dioxide content of the atmosphere has increased continuously since 1700, and currently by ca. 1 ppm/a. The volume concentration today is 355 ppm, the total amount added annually being 22 × 10^9 t [663]. As with CO_2, the global concentrations of CH_4, H_2, CO, and O_3 are also increasing, but only in the northern hemisphere (Table 28) [662].

Table 28. Concentration trends of chemically reactive trace substances [X]*

X	[X], ppbv	Increase above preindustrialized period, %	Annual increase, %
CO	NH: 100 – 150		NH: 1 [679]
	SH: 50 – 70		SH: ≈0 [679]
CH_4	1700	130	1 [679]
H_2	512		0.6 [679]
O_3	NH: 40 – 45**	160	NH: 1 [679]
	NH: 20 – 30***		SH: ≈0
Nitrate		100 [680]	
Sulfate		100 [680]	
H_2O_2	0.2	50 [681]	
·OH	ca. (2 – 3)×10^{-5} ?		?

* NH = Northern hemisphere; SH = Southern hemisphere.
** Free troposphere.
*** Near ground level.

8.3. Reaction Cycles in the Atmosphere (see also Chap. Physics and Chemistry of the Atmosphere)

The atmosphere contains a total of ca. 5 × 10^{18} kg air, of which 3 × 10^{18} kg make up the troposphere. The reactions above and below the tropopause differ, and there is almost no mass transfer between troposphere and stratosphere. Emissions take part in chemical transformations in the troposphere, and eventually return to the earth's surface, partly by transport reactions, but mainly as mineralized substances.

The atmosphere obtains its energy from solar radiation, which amounts to 3.7 × 10^{23} kW, or 3.2 × 10^{27} kW · h/a. Of this a light flux of 1.6 × 10^{18} kW · h/a is incident on the stratosphere. After passing through the ozone layer, where light is absorbed in the wavelength range below 300 nm, 8 × 10^{17} kW · h/a passes into the troposphere and to the earth's surface.

8.3.1. *The Troposphere*

Material cycles in the troposphere are partly mass-transfer cycles with a high energy requirement and partly chemical transformation processes involving reactive intermediates formed photochemically. These cycles are partly interlinked, especially the water cycle and the carbon cycle.

The amount of water entering the troposphere annually is 4.6 × 10^{17} kg, of which 4.0 × 10^{17} evaporates from the oceans and 0.6 × 10^{17} from the land surfaces. This corresponds to an energy of 3 × 10^{17} kW · h, which is released as heat of condensation on cloud formation and precipitation. The largest part of the carbon cycle is accounted for by CO_2, with a concentration in air of 0.034 vol % at sea level and a turnover of 8.3 × 10^{14} kg/a. Of this, 3.7 × 10^{14} kg CO_2 takes part in a

direct partial cycle with the ocean.

The degradation of organic compounds, as well as other oxidation processes there, in the troposphere is initiated by only a small number of photochemical primary reactions. Very few reactions act as radical sources, as only light of wavelength ≥ 300 nm reaches the lower atmosphere [662].

The fundamental reactions are:

1. Photolysis of nitrogen dioxide at 400 nm

   $$NO_2^{\bullet} \xrightarrow{h\nu} NO^{\bullet} + O:$$

   followed by the formation of ozone

   $$O: + O_2 \xrightarrow{M} O_3$$

   where M is a collision partner, an inert molecule that absorbs energy without itself being chemically changes.
2. Photolysis of ozone at 300 nm with formation of excited oxygen atoms

   $$O_3 \xrightarrow{h\nu} O_2^*(^1\Delta g) + O^*(^1D)$$

   followed by formation of the hydroxyl radical

   $$O_*(^1D) + H_2O \rightarrow 2 \cdot OH$$

3. Oxidation of carbon compounds, ultimately of CO

   $$HO\cdot + CO \rightarrow H\cdot + CO_2$$

   followed by formation of the peroxyhydroxyl radical and regeneration of nitrogen dioxide and hydroxyl

   $$H\cdot + O_2 \rightarrow HO\cdot_2$$

   $$HO\cdot_2 + NO\cdot \rightarrow \cdot OH + NO\cdot_2$$

This regeneration ensures that the oxidation rate in the troposphere is maintained.

Together with VOCs complex reaction mechanisms result.

Radical reactions in the system CH_4 + CO + air + NO_x + $h\nu$ are listed in the following Radical source

$$O_3 + H_2O + h\nu \rightarrow 2 \cdot OH + O_2$$

Radical transformation: HO· ⟶ $HO\cdot_2/CH_3O_2$

$$\cdot OH + CO + O_2 \rightarrow CO_2 + HO\cdot_2$$

$$\cdot OH + CH_4 + O_2 \rightarrow CH_3O\cdot_2 + H_2O$$

$$2\,CH_3O\cdot_2 + O_2 \rightarrow 2\,HO_2 + 2HCHO$$

$$\cdot OH + O_3 \rightarrow HO\cdot_2 + O_2$$

Radical regeneration: $HO\cdot_2/CH_3O_2$ ⟶ ·OH

$$HO\cdot_2 + O_3 \rightarrow \cdot OH + 2\,O_2$$

$$HO\cdot_2 + NO \rightarrow \cdot OH + NO_2$$

$$CH_3O_2 + 2NO + O_2 \rightarrow \cdot OH + 2\,NO_2 + HCHO$$

$$(\text{via } CH_3O\cdot + O_2)$$

Radical loss

$$\cdot OH + NO_2 \rightarrow HNO_3$$

$$HO\cdot_2 + HO\cdot_2 \rightarrow H_2O_2 + O_2$$

$$HO\cdot_2 + CH_3O\cdot_2 \rightarrow CH_3OOH + O_2$$

$$2\,CH_3O\cdot_2 \rightarrow CH_3OH + HCHO$$

Ozone formation

$$NO_2 + O_2 + h\nu \rightarrow NO + O_3$$

Some intermediates react with one another, with already formed photooxidants, or with direct photolysis products of certain VOCs, e.g.,

$$H_2CO \xrightarrow{h\nu} H^\bullet + HCO^\bullet$$

$$HCO^\bullet + O_2 \longrightarrow HO_2^\bullet + CO$$

These radical-loss reactions lead to oxidation products which are washed out by precipitation.

Oxidation of VOCs during the day proceeds via radical chains (Fig. 109 A), and at night via the $NO\cdot_3$ radical (Fig. 109 B).

Figure 109. VOC oxidation by ·OH/·O_2H radical chain

A) Day time chemistry ; B) Night time chemistry

The atmospheric oxygen that takes part in the reaction is present in excess and is not shown in the reaction scheme

The continuous regeneration of oxidizing species consumed in oxidation, especially the ·OH radical, depends basically on the concentration of the nitrogen oxides. With increasing emissions of organic compounds, emissions of NO_x ought also to increase to ensure their degradation [661]:

$$HO\cdot_2 + NO\cdot \rightarrow \cdot OH + NO\cdot_2$$

$$RO\cdot_2 + NO\cdot \rightarrow RO\cdot + NO\cdot_2$$

$$HO\cdot_2 + NO\cdot_3 \rightarrow \cdot OH + NO\cdot_2 + O_2$$

$$RO\cdot_2 + NO\cdot_3 \rightarrow RO\cdot + NO\cdot_2 + O_2$$

In this context, tropospheric ozone plays an ambivalent role. Depending on its concentration and that of other trace substances, especially nitrogen oxides, it is an essential provider of excited oxygen atoms, which form hydroxyl radicals and hence cause degradation of VOCs. However, ozone formed in the same way in photosmog causes formation of the nitrogen-containing components of the photooxidants. At lower NO_x concentrations (i.e., <10 ppt), ozone is consumed, and at higher NO_x concentrations (i.e., up to 10 ppb), O_3 and ·OH are continuously regenerated. Above 10 ppb, ·OH radicals are captured by NO_2 radicals and the chain is broken.

Ozone-forming and ozone-decomposing reactions are summarized in the following:

Ozone formation

$$NO_2 + O_2 + h\nu \rightarrow O_3 + NO$$

$$O_3 + NO \rightarrow O_2 + NO_2$$

$[O_3] = c\,J\,[NO_2]/[NO]$, photochemical equilibrium, J = photolysis frequency

$$RO\cdot_2 + NO \rightarrow RO\cdot + NO_2$$

$$HO\cdot_2 + NO \rightarrow \cdot OH + NO_2$$

These two reactions cause the $[NO_x]/[NO]$ ratio to increase without consuming O_3 Critical competitive reactions which retard the oxidation of NO:

$$HO\cdot_2 + HO\cdot_2$$

$$HO\cdot_2 + RO\cdot_2$$

$$RO\cdot_2 + R'O\cdot_2$$

$HO\cdot_2 + O_3$

$RO\cdot_2 + O_3$

$RO\cdot_2 + NO \rightarrow RONO_2$

Destruction of radicals on surfaces and in raindrops $RO_2 + NO_2 \longrightarrow RO_2NO_2$ (only transitory, as thermal decomposition occurs; stable alkyl nitrates can be formed on surfaces)

		Ozone loss
$O_3 + h\nu$ (λ < 310 nm) $\longrightarrow O(^1D) + O_2$		30 %
$O(^1D) + H_2O \longrightarrow 2 \cdot OH$		
$\cdot OH + O_3 \longrightarrow HO\cdot_2 + O_2$		
$HO\cdot_2 + O_3 \longrightarrow \cdot OH + 2\,O_2$	(HO_x cycle)	30 %
Overall: $2\,O_3 \longrightarrow 3\,O_2$		
$RO\cdot_2 + O_3 \longrightarrow RO\cdot + 2\,O_2$	(with low NO_x)	
Alkenes + $O_3 \longrightarrow$ products		<2 %
$NO_2 + O_3 \longrightarrow NO\cdot_3 + O_2$	(night time)	<1 %
Dry deposition		ca. 25 %

In the case of photochemical degradation in the troposphere above densely populated areas, the lifetimes and residence times of photooxidants are important evaluation criteria together with the emission rates of nitrogen oxides and VOCs [661]. With large-area emission sources such as dense motor traffic and combustion in general, the chemistry and physics of the photosmog form the decisive basis for technical and administrative action.

Some lifetimes τ (298 K, 1 bar) for the reaction $RO_2NO_2 \longrightarrow RO_2 + NO_2$ are:

Ethyl peroxynitrate ($C_2H_5O_2NO_2$)	0.3 s
Acetyl peroxynitrate ($CH_3C(O)O_2NO_2$)	2174 s (0.6 h)
Acetonyl peroxynitrate ($CH_3C(O)CH_2O_2NO_2$)	0.4 s

The mean ozone volume concentration in the free troposphere of the northern hemisphere is 40 ppb (80 µg/m^3), which is three times that of 100 a ago, and is mainly due to anthropogenic emissions of nitrogen compounds. However, these are needed to degrade the increasing emissions of organic compounds, including methane and carbon monoxide, by continuously forming oxidizing species in the troposphere.

The ozone in the troposphere takes part in a complex series of reactions, and is to a degree indispensable to maintain the purity of the lower atmospheric strata. However, these chemical processes and their significance are entirely different from those of the ozone of the stratosphere. If an interaction between the two strata does exist, the possible role of ozone must again be considered. Although this substance is formed differently in the two strata, has different effects, and is not involved in mass-transfer processes, there is an indirect relationship between the ozone in the troposphere and that in the stratosphere (see Section The Stratosphere).

A further contribution to atmospheric photochemical degradation is made by halogen chemistry. Halogenated alkanes and volatile halogenated organic compounds in general are mostly degraded fairly rapidly, similar to chlorine-free organic compounds, though some are degraded relatively slowly [652], [661], [682]. These processes are directly relevant to questions raised by some trace substances which are not degraded particularly rapidly in the troposphere, have high vapor pressures (e.g., fluorinated hydrocarbons; see Section Measurement and Computation of Degradability), and as a result can therefore pass into the stratosphere. Degradable halogen is converted to hydrogen halide, and is washed out of the troposphere by precipitation.

A direct contribution to photochemical degradation in the lower strata of the atmosphere above the oceans and coastal regions (extending as far as 100 km inland, depending on the wind) is made by entrained sea spray. An aerosol is formed and a photochemical reaction, mainly with NaCl, then forms Cl atoms, which degrade organic trace substances in the troposphere more rapidly than · OH radicals [653].

Of the large mass cycles, that of carbon and its compounds forms the foundation for living matter. It is dominated by carbon dioxide [649], which at a concentration of 0.034 vol % in the atmosphere, amounts to 2.6×10^{12} t, with an annual turnover of 830×10^9 t and a mean residence time of 3.3 a.

The turnovers of photochemical partial cycles are comparatively small.

Entry of carbon compounds into the atmosphere (in 10^9 t) is as follows:

CO_2 from respiration of biomass	220	
CO_2 from putrefaction of biomass	220	
(formation on biomass by photosynthesis)		440 (removal)
CO_2 from the sea	365	
Returned to the sea (equilibrium)		365 (removal)
CO_2 from forest clearance	7	
CO_2 from combustion processes	18	
CO_2, total emission	830	
CO, total emission	3.4	
CH_4, total emission	0.5	
C (in VOCs), total emission	1.0	

Worldwide efforts to reduce CO_2 emission are intended to

1. Reduce the greenhouse effect
2. Save energy
3. Conserve resources of carbon-containing fossil fuels, partly to retain them as chemical raw material

Since, the majority of anthropogenic CO_2 emissions are produced by combustion processes, which simultaneously produce NO_x, a decrease in CO_2 would also be associated with a decrease in NO_x and hence in tropospheric ozone. Decreases in the concentration of hydrocarbons and nitrogen oxides would immediately lead to a noticeable reduction in the concentration of ozone, as its lifetime in the lower atmosphere is short.

8.3.2. *The Stratosphere*

The most important trace gas in the stratosphere is ozone. It is contained in a layer 25 –30 km thick in the lower stratosphere at a latitude-dependent concentration of 10^{12} cm^{-3}. This accounts for 90 % of the total atmospheric ozone [657, 658, 679, 683, 684]. Ozone is mainly produced above the equatorial regions and is transported towards the polar regions. Its existence depends on a delicate equilibrium between formation and degradation, and it is essential that its concentration in the stratosphere should be maintained for the benefit of climatic and living conditions on the earth's surface. Stratospheric photochemical degradation of volatile substances emitted into the troposphere but are degraded so slowly there that they migrate to the stratosphere would lower the stratospheric ozone concentration and lead to impaired conditions at the earth's surface.

Ozone is formed in the stratosphere exclusively by the photolysis of oxygen.

$$O_2 \xrightarrow[\lambda \leq 250\ nm]{h\nu} 2\,O$$

$$O + O_2 \xrightarrow{M} O_3$$

The inert collision partner M is provided from the surrounding supply of O_2 or N_2 molecules. Photolytic degradation then follows, but caused by light of a longer wavelength

$$O_3 \xrightarrow[\lambda \geq 300\ nm]{h\nu} O_2 + O$$

$$O + O_3 \longrightarrow 2\,O_2$$

A chemical degradation process also exists

$$Y + O_3 \rightarrow O_2 + YO$$

$$YO + O \rightarrow O_2 + Y$$

The net reaction is thus

$$O + O_3 \rightarrow 2\,O_2$$

In the natural stratosphere, Y = ·OH and YO = $HO\cdot_2$. The natural ozone concentration is formed in this way.

The exhaust gases from supersonic aircraft, rockets, and the undecomposed components of emissions from the earth's surface ascending through the troposphere can provide further reactive species that can take part in ozone degradation and affect the above-mentioned equilibrium concentration:

$$Y = NO, Cl\cdot, Br\cdot$$

$$YO = NO_2, ClO\cdot, BrO\cdot$$

In this system, the transformation of ·OH into $HO\cdot_2$ and back again takes place very rapidly (Fig. 110).

Figure 110. HO_x chemistry of the stratosphere

H_2O_2 and HOCl are formed and act as temporary sinks, while nitric acid and water act as permanent sinks. If these degradation reactions consume ozone more rapidly than it is regenerated or replaced by transport mechanisms, which is regularly the case in the region of the antarctic polar cap, this leads to a transitory but periodically recurring decrease in the concentration of stratospheric ozone (Fig. 111).

Figure 111. Scheme of the chlorine-induced cycle causing degradation of ozone in the global stratosphere

This can lead to a 50 % depletion of the normal ozone layer over an area the size of Antarctica — the so-called ozone hole (Fig. 112).

Figure 112. Meteorology and chemistry of antarctic ozone depletion

The chlorine compounds HOCl, $ClONO_2$, HCl, and elemental chlorine are formed from ascending CFCs and chlorine injections from the boosters of rocket carriers [685].

The ozone hole starts to form at the end of the antarctic winter by mid September and disappears again by mid November. It is preceded by a rapid cooling of the stratosphere to – 80 °C in June and July. This causes formation of polar stratospheric clouds (PSCs), one type of which consists of nitric acid, hydrochloric acid, and water, and the other exclusively of water. The latter type is larger and leads to precipitation and hence dehydration of the polar stratosphere. In a reaction that takes place at the surfaces of the PSCs, $ClONO_2$ forms Cl_2, HOCl, and HNO_3. This amounts to condensation of the nitrogen species into sinks but to a redistribution of the chlorine species from less active sinks into more reactive species (see Figs. 110 and 111).

The degradation of emissions that have entered the stratosphere also leads to the degradation of the stationary reaction partner ozone. The direct result is an increase in the UV-B radiation at the earth's surface, and an indirect result is increased permeability of the stratosphere towards other emissions ascending from the troposphere. This would be enabled by cooling of the stratosphere due to the loss of the ozone.

8.4. Interaction with Surface Layers of Aquatic and Terrestrial Environments

Under the influence of sunlight, active oxidizing agents are formed in water [686] with the following concentrations (mol/L):

Hydroperoxyl ($HO\cdot_2$)	$10^{-9} – 10^{-8}$
Peroxyalkyl (ROO·)	$10^{-11} – 10^{-10}$
Singlet molecular oxygen	$10^{-14} – 10^{-13}$
Hydrated electron	$10^{-17} – 10^{-15}$
Hydroxyl (·OH)	

$10^{-18} – 10^{-19}$

Of these, the hydroxyl radical, with 10^6 radicals per cubic centimeter down to a depth of ca. 1 m [687], is the most significant for photochemical degradation in water as well as in air. The concentration is comparable to that in air, but can be lower in pure water or pure natural water bodies [688]. In natural surface water, the most important source of ·OH is the photolysis of nitrate.

Dissolved or dispersed organic compounds or inorganic compounds in lower oxidation states are also oxidized in the aqueous phase by indirect photochemical degradation. These processes are similar to those that take place in the mixture of hydrogen peroxide and iron(II) salts known as Fenton's reagent, in which intermediate stages also involve radicals (see ⟶ Wastewater). Reactions of this type can already take place with constituents of natural surface water. For example, in seawater the bromide ion is oxidized to hypobromite, and in the layers near the surface of fresh water the humic matter present at a concentration of 1 – 10 mg/L is oxidized to form oxidizing radicals such as RO·, $RO·_2$, and $HO·_2$.

Most rate constants for the reaction of organic compounds with ·OH radicals in water have values of the order of $k_{OH} \approx 10^9$ L mol^{-1} s^{-1} [689]. The rate constants of other reactions show a similar scatter around the mean figure [687], e.g., K_{OH} values in air (see Section Lifetime in the Homogeneous Gas Phase).

k_{OH} (L mol^{-1} s^{-1}) values for some compounds in water follow:

Urea	2.1×10^6
Acetonitrile	3.5×10^6
Chloroform	8.5×10^6
Ethylene oxide	4.0×10^7
Methanol	8.9×10^8
Thiophene	3.3×10^9
Phenol	1.6×10^{10}
Aniline	1.7×10^{10}

The dependence on solar radiation is more pronounced than in the case of air (Table 29) [688].

Table 29. Lifetime of ·OH in surface (fresh) water

Substance	τ (sun) [a], h	τ (average) [b], h
Aniline, phenol	14, 5	6.37×10^3
Methanol	320	10.43×10^4
Chloroform	33 000	12.46×10^6

[a] Optimum conditions (intense sunlight, at water surface) [·OH] ≈ 10^{-15} mol/L.
[b] With annual average values ⟨[·OH]⟩ ≈ 3×10^{-18} mol/L. The time for (a) is hours of intense sunlight, for (b) it is "real" time.

In water droplets, fog, dew, etc., or on the earth's surface, the situation is similar, and the substances in these environmental compartments do not have a high vapor pressure. In the vapor-pressure range from 10^{-7} to 1 Pa they are referred to as semivolatile organic compounds (SOCs) [690]. For the photochemical degradation of these substances, not only the formation but also the distribution of the photooxidants is of direct relevance [691]. In the interaction between biotic and abiotic degradation steps of the aquatic systems of rivers, lakes, and wet ground, and mass transfer into the troposphere at ground level, the photochemical degradation of organic substances in water makes a contribution to the total mineralization [654, 656, 687, 690, 691].

8.5. Measurement and Computation of Degradability

To derive ecological relationships from the properties of chemical substances, their biotic and abiotic interactions must be considered. The behavior of a substance in the environment is determined and assessed by drawing on the results of ecotoxicological investigations (see ⟶ Ecology and Ecotoxicology). However, only since the late 1970s has it been possible to answer a fundamental aspect of this question, i.e., how long a substance exists in the atmospheric environment. This came with the development of reliable measurement techniques and equipment.

With regard to the biotic degradation pathways in the carbon cycle (see Chap. Physics and Chemistry of the Atmosphere), the reaction chains, mechanisms, and rates in the water and soil environmental compartments are well known in many cases, and provide a working knowledge for science, economy, administration, and legislation. An abiotic process in the

atmosphere was only confirmed with the development of laboratory methods that supplemented earlier field tests of mainly meteorological interest. Besides benefiting from progress in other fields, especially the various types of laser spectroscopy, a number of techniques have been developed specifically for investigating photodegradation.

In the environmental compartment troposphere, degradability (or its converse, chemical persistence) is characterized by abiotic processes which are photochemically induced and then proceed in oxidative steps. Degradability is determined by

1. The concentration of the oxidizing agent in the troposphere, sometimes in a particular locality and at a particular time
2. The rate constants of the reaction with a reaction partner which is volatile and homogeneous in the gas phase or is bonded to particles as an aerosol

There is now much data on both factors. A number of experimental methods have been developed for determining rate constants, and figures for K_{OH} are now available for 600 compounds in air, as are rate constants for other oxidizing agents in other media and in heterogeneous phases. Rate constants for photochemical degradations are available in spreadsheets [693-695] and data banks [696]. Values for K_{OH} can also be derived from bond energy increments of individual structural groups and classes of substances [697-699].

The chemical lifetime is found from the rate constants of bimolecular reactions. The degradation rate of substance X

$$-\frac{\mathrm{d}\,c_{(X)}}{\mathrm{d}t} = k\,c_X c_Y$$

and the rate constant k are both expressed as cm^3 per molecule per second (cm^3/s). It depends on temperature and pressure. It is simplified by incorporating c_Y, the time-averaged concentration of the oxidizing agent, into the constant, and a new monomolecular rate constant K is derived:

$$K = k\,c_Y$$

The degradation rate is then given by

$$-\frac{\mathrm{d}\,c_X}{\mathrm{d}t} = K\,c_X$$

Sometimes, the less obvious term “chemical half-life” ($\tau_{1/2} = 0.69\ \tau_X$) is used, i.e., the time for the concentration of the starting material to reach half its initial value. However, this is dependent on the physicochemical environment of a substance, and is thus not a property inherently characteristic of a substance like the half-life for radioactive decay, which is unaffected by outside influences. The residence time in the atmosphere is usually smaller than the chemical lifetime because in some cases part of the undecomposed material can be removed by transport processes.

The main primary oxidizing agents in the troposphere are ·OH, $HO\cdot_2$, O_3, and $NO\cdot_3$. The ·OH radical is present at rather low concentration, but reacts so much more rapidly than the other oxidizing agents that it has been found possible to deduce the chemical lifetime of a substance in the troposphere solely from its rate constants [690].

The limits of measurability are:

K_{OH} values	Corresponding chemical lifetime
10^{-10} cm^3/s for rapid reactions	1 h
10^{-16} cm^3/s for slow reactions	130 a

To measure rate constants of the photochemical degradation of a substance in the atmosphere, a vapor pressure of >1 Pa is required in the laboratory to give a sufficiently high concentration of the substance in the photoreactor [689], [699]. Nonvolatile compounds are first adsorbed on an inorganic carrier, and the adsorbate is then investigated as an aerosol in a smog chamber [653], [672]. This method has the advantage that it simulates a real dust-laden atmosphere, and any catalytic acceleration of the photochemical degradation by traces of heavy metals in the carriers can be measured. This also applies to the use of TiO_2 as a carrier for the test aerosol [672].

If only the rate constant K_{OH} is to be determined, this can be carried out in aqueous solution with H_2O_2 as the source of ·OH radicals [689] at a stationary concentration of $c_{OH} = 5 \times 10^{-14}$ mol/L or 4×10^7 cm^{-3}. For SOCs, which usually are only sparingly soluble in water, 1,1,2-trichlorotrifluoroethane can be used as solvent [692], with H_2O_2 as ·OH source.

A guideline for the standardization and international harmonization of test methods and standards for photochemical degradation in air [699] and water [700] has been produced by the OECD countries. Methods for the derivation of rate constants from structural increments have also been produced.

8.5.1. *Lifetime in the Homogeneous Gas Phase*

The various important naturally-occurring oxidizing agents can be present in widely different concentrations. The effects of

the intensity and duration of the solar radiation can also differ widely (Table 30) [690].

Table 30. Concentration of oxidizing agents

Molecules/cm^3	Day	Day/night	Night
·OH	1×10^6	0.5×10^6	
O_3	1×10^{12}		
NO·$_3$	instable	1.5×10^8	2.5×10^8

The NO·$_3$ radical is rapidly photolyzed and is therefore mainly active at night. It forms nitric acid by hydrogen abstraction and undergoes addition to double bonds.

In the medium lifetime range (ca. 10 d) the fluctuation in ·OH concentration caused by irregular radiation is sufficient to cause significant differences in rate of degradation (Table 31) [661], [687].

Table 31. Chemical lifetimes of some volatile organic compounds in the troposphere*

Compound	Chemical formula	*k* values for ·OH, 10^{-12} cm^3/s	Lifetime, d	
			Tropics	Global
Ethane	C_2H_6	0.29	20	61
Methanol	CH_3OH	0.80	6.5	15
Acetylene	C_2H_2	0.90	5.5	13
Benzene	C_6H_6	1.31	4.5	12
Propane	C_3H_8	1.59	3.6	11
n-Butane	C_4H_{10}	2.4	2.1	7.5
Isobutane	C_4H_{10}	2.3	2.2	8
Dimethyl ether	CH_3OCH_3	2.6	1.9	7
Ethyl alcohol	C_2H_5OH	3.0	1.8	5.9
n-Pentane	*n*-C_5H_{12}	3.7	1.5	4.8
Toluene	$C_6H_5CH_3$	6.19	0.9	2.8
Ethylbenzene	$C_6H_5C_2H_5$	7.73	0.75	2.5
Ethene	C_2H_4	7.85	0.7	1.9
Formaldehyde	HCHO	10	0.5	0.9
o-Xylene	$C_6H_4(CH_3)_2$	14	0.35	0.7
Acetaldehyde	CH_3CHO	16	0.3	0.6
Propene	C_3H_6	29	0.2	0.4

* ·OH concentration: 2×10^6 cm^{-3} at 24 h mean in tropical regions, 6.5×10^5 cm^{-3} as global mean; O_3 concentration: 30 ppbv.

A relationship between K_{OH} values and chemical structure is only observed with homologues [653], [693]. The first member reacts much more slowly than the rest (Table 32). Photochemical degradation by ozone also shows no dependence on chemical structure [653], [701]. Alkenes and other substances with olefinic double bonds are significantly degraded by ozone, but other compounds containing multiple bonds and aromatics are degraded rather slowly (Table 33).

Table 32. Rate constants k (in 10^{-12} cm^3 s^{-1}) for the reactions of ·OH with various organics at room temperature

Compound	Ref. [653]	Ref. [693]	Compound	Ref. [653]	Ref. [693]

3,3-Dimethylpentane	3.7				

Table 33. Rate constants, k (in 10^{-17} cm^3 s^{-1}), for the reaction of ozone with various organics at room temperature

Compound	Ref. [653]	Ref. [701]
Propene	1.1	1.13
Isobutene	1.3	1.21
1-Pentene	0.95	1.1
1-Hexene	1.1	1.17
1-Heptene	1.15	0.8 – 1.7
1-Octene	1.25	0.8
1-Nonene	1.45	
Vinyl chloride	0.014	0.017 – 0.2
Acrylonitrile	0.002	
Propionitrile	<0.001	
Butyronitrile	<0.001	
o-Xylene	<0.007	7×10^{-5}
p-Xylene	<0.01	4×10^{-5}

The rates of degradation of chlorinated hydrocarbons also do not show any correlation with structure [702]. They include very slowly degraded substances with lifetimes of several years and typical ones with lifetimes of around 14 d (Table 34).

Table 34. Tropospheric concentrations and lifetimes of some chlorinated hydrocarbons

Compound	Troposheric concentrations, pptv	Tropospheric lifetimes, a
C_2HCl_3	16	0.04
C_2Cl_4	40	0.4
$CHCl_3$	15	1
CH_3Cl	600	2 – 3
CH_3CCl_3	110	5 – 10
CCl_4	120	60 – 100

The large number of K_{OH} values known show that degradability rate constants of organic compounds can have a range of six orders of magnitude. Most organic compounds have a photochemical lifetime within a range of two orders of magnitude, i.e., a lifetime of 1 – 100 d. Some are degraded within hours, and a few require more than a year (Fig. 113). If

the lifetime exceeds 10 a, ascent from the troposphere into the stratosphere has to be taken into consideration [661].

Figure 113. Chemical lifetimes of organic compounds in the atmosphere

Standardized graphical and tabular presentations are usually based on a concentration of 0.5 × 10^6 ·OH radicals/cm^3 as a basis for K_{OH} values and lifetimes.

8.5.2. *Lifetimes of Adsorbates Aerosols*

A portion of natural and anthropogenic emissions reach the troposphere bound to aerosol particles. Experimental investigations in an aerosol/smog chamber with a volume of 2.4 m^3 [653], [672] have shown that the degradation rate of nonvolatile substances transported into the atmosphere in adsorbed form is comparable to that of volatile substances in a homogeneous phase.

The aerosols have a multilayer structure. Surrounding a water-insoluble core of, for example, desert dust, fly ash, volcanic ash, is a salt-containing aqueous envelope onto which the organic trace substances are adsorbed, with the hydrophilic ends of the molecules directed inwards. The hydrophobic groups directed outwards hinder the penetration of hydrophilic gases such as acids and tend to keep the aerosol in suspension [704].

Most of the global total of (1 – 2) × 10^9 t of aerosol is formed by sodium chloride from sea spray. Some of the chlorine is transformed photolytically to chlorine-containing reactive species. Hence a photo-induced degradation of emissions in the troposphere also takes place in this way. The reaction can be measured in a smog chamber [653], [672]. The k_{Cl} rate constants found are in agreement for various Cl sources [703]. The degradation process is about two orders of magnitude more rapid than that via OH· radicals (Table 35).

Table 35. Rate constants k (in 10^{-10} cm^3 s^{-1}) for the reaction of chlorine atoms with various organics

Compound	Source*			Ref. [703]
	I [653]	II [653]	III [653]	
Propene	1.09		1.02	1.34
n-Butane**	1.97	1.97	1.97	1.97
n-Pentane	2.65	2.50	2.35	2.52

1,1-Dichloroethene	2.10			
Benzene	0.05			0.15
Toluene	0.74	0.66		0.589

* Source of Cl: NaCl aerosol in photosmog (I); photolysis of Cl_2 (II), photodegradation of chlorobenzene, vinyl chloride, trichloroethene and 1,1-dichloroethene (III).
** Reference compound.

A further decrease in the lifetime is observed if the airborne dusts of the aerosols contain heavy metals, have semiconducting properties, or can react in redox systems. With pure titanium dioxide as the carrier particle, the ·OH concentration is increased by a factor of ten, and the degradation rate is correspondingly increased (Fig. 114) [653], [672].

Figure 114. Typical formation of ·OH in an aerosol smog chamber in the presence of SiO_2 or TiO_2 aerosol

In the absence of aerosol the formation of ·OH is similar to the curve observed in the presence of SiO_2

This reaction principle is also used in aqueous suspensions [705] (see ⟶ Wastewater). Multiphase systems are important in addition to airborne aerosols in the earth – air boundary region (see Section Reaction Cycles in the Atmosphere).

8.5.3. *Assessment and Evaluation*

Photochemical degradation is of major and direct importance because it eliminates substances that enter the atmosphere as emissions from natural and anthropogenic sources or from products used in the open. Some of these substances are considered to affect the climate, others to be detrimental to the filtering effects of the ozone layer on the UV-B fraction of sunlight, and many others to be pollutants of soils and bodies of water on the earth's surface, from where they can return to the atmosphere.

The question of the whereabouts of a substance in a given environment [687], [706] is largely tantamount to enquiring about its compatibility with conditions prevailing in that particular environmental compartment; holistic considerations contribute greatly [707-710].

Moreover, it is processes much more than states which furnish the determinants. Already the environmental concentration of a substance is merely the difference between two rates, that of input and that of output. In that sense, cross sections of an environment are better expressed by mass and energy fluxes than by properties of any particular substance or a group of substances.

Data on individual substances are much less suitable for describing the status of the environmental compartment “air”. Instead they express the oxidative sensitivity of a substance in sunlight as a first step towards mineralization [711].

1. Definition

Stephen Nortcliff

Soil is normally considered as the fine earth which covers land surfaces as a result of the in situ weathering of rock materials or the accumulation of mineral matter transported by water, wind, or ice. The distinctive feature of soil is that to this weathered mineral material is added organic material. This organic material may be both living and dead. The dead organic matter will include little altered and freshly added dead plant roots and leaf and other plant litter, dead fauna, and organic material in various stages of decomposition from little modified relatively fresh materials to the complex decomposed material called humus. It is this mixture of mineral and organic material which gives the soils their distinctive characteristics. Across the surface of the earth there are many different types of soil which reflect, at least in part, varying combinations of mineral and organic matter and their differing responses — both separately and often in complex association — to different environmental conditions. Indeed soil (and the soil constituents), together with the plant life it supports, the rock on which it lies, and the climate it experiences, forms a finely balanced system.

Depending upon the context, the word “soil” may have very different meanings. A simple definition of soil is the material that plants grow in and which provides them with physical support, water, and nutrients. There are other more particular uses of the term soil. To the engineer, soil is the finely divided and relatively loose “rock” material at the earth's surface, and this overburden is often considered an inconvenience because it must be removed. The geologist calls this layer the regolith and geological investigations frequently begin below it. The hydrologist looks on the soil as if it were a large reservoir storing water to supply streams and rivers. The most widely held view of the soil, however, is as a medium for plant growth and the provision of food and fiber directly or through the intermediate stage of animals.

Soil is important as a medium for plant growth and for the support of much animal and human activity. The soil acts as a reservoir for nutrients and water providing the plants' needs for these requirements throughout their growth. The soil may also provide an environment for the breakdown and immobilization of materials added to the surface (in addition to the aforementioned plant and animal remains) such as fertilizers and pesticides and waste products such as sewage sludge, animal wastes and slurries, and composted refuse materials. The soil is a complex dynamic system in which the interactions of the biological, chemical, and physical environments results in the transformation of materials, possibly rendering initially harmful materials less dangerous and immobilizing others as a result of the interactions between these added materials and the organic and inorganic soil constituents. This immobilization may enable breakdown of the potentially dangerous materials to less dangerous forms. These interactions and transformations may be long term, over decades, medium term over months or years, short term between individual events such as rainstorms, or almost instantaneous.

The soil usually consist of a vertical sequence of layers or horizons differentiated by physical, chemical, or biological characteristics. This sequence of layers is normally described as the soil profile. Surface horizons are usually characterized by accumulations of organic materials as a result of the addition of plant and animal residues (it is, however, becoming increasingly apparent that organic additions in deeper layers from roots may have a significant role to play in the overall additions of organic material and in the operation of the soil processes). Surface horizons with a mixture of mineral and organic materials are usually identified as *A horizons* and may be further described by the amount and nature of the organic matter present within the horizon. Where there is a substantial proportion of organic material in the surface layer it may be called *O horizon*. The A and O horizons are generally considered the biologically most active part of the soil and are also subject to considerable changes as a result of the weather, being frequently exposed to wetting and drying cycles and to a wide range of temperatures, which results in high rates of activity in physical and chemical processes. Both organic and mineral materials are transformed in these surface layers and frequently some of the byproducts of these transformations are released and removed to lower layers within the soil (eluviation). Below the A horizons usually *B horizons* are encountered where the balance shifts from predominantly biological processes as in the A horizons to predominantly chemical and physical processes. Pedologists normally consider this zone to be that of peak activity of the pedological or soil-forming processes, and it is for this reason that many of the currently used soil classifications pay particular attention to the characteristics of the B horizon in the allocation of soils to classes. The B horizons are frequently subject to the maximum intensity of weathering processes and transformations and may also exhibit the accumulation of materials translocated from surface layers (illuviation) such as clays, organic matter, and iron and aluminum hydrous oxides. The description of B horizons frequently emphasises the degree of weathering and the nature of the accumulated materials. The *C horizon*, below the B, is the relatively unaltered material from which the A and B horizons may have developed.

The importance of the incorporation and breakdown of organic matter and the production of complex organic materials, as well as the weathering of mineral materials to produce secondary products (such as clay minerals) and to release minerals which may be taken up by plants or leached out of the system, provides the distinctive nature of the soil. In particular the large surface area associated with soil materials and their ability both to retain and exchange ions (both those added in fertilizers and those released during weathering and biological decomposition) and to absorb water are important properties which distinguish soil from rock materials.

The soil performs many functions. These include functions related to natural ecosystems, agricultural productivity, environmental quality, soil as source of raw materials and as base for buildings. Of these the agricultural productivity function is probably the most widely recognized and understood. This function of soil is to support plant and animal productivity whilst maintaining or enhancing water and air quality and also supporting human health and habitation. To perform this production function, the soil must be able to provide the following: a physical, chemical and biological context suitable for the survival and development of living organisms; the conditions for the regulation and partitioning of water flow, storage and recycling of nutrients and other elements; conditions to support biological activity and diversity for plant growth and animal productivity; an environment to filter, buffer, degrade, immobilize, and detoxify organic and inorganic substances; and provide mechanical support for living organisms and their structures. This brief list of requirements illustrates the complex demands placed upon soil if it is to maintain the productivity which is essential if the food demands of an ever growing global population are to be met. It further illustrates the need to understand the complex interactions between the various components within the soil and the interactions with other components of the terrestrial ecosystems. The productivity functions of soil is probably the most widely studied and understood, but the soil is increasingly expected to perform functions related to the maintenance of environmental quality, such as the filtering of toxic materials applied to the soil surface. If the soil is to perform these varied functions effectively and with no reduction in its overall quality the role of the soil, its components and processes must be investigated and understood. It must be ensured that in performing one function the soil's ability to perform other functions is not reduced or removed.

Soil is essential for many human activities. It is also a basic part of the natural environment. The development of humans and society since prehistoric times has been closely linked with an increasing ability to manage the soil to human benefit. This progress has been achieved by adjusting the balance between the soil and its natural environment. These adjustments have not always resulted in positive responses and benefits, and there are records throughout history describing soil destruction as a result of mismanagement and misuse of the soil, often as a result of the failure to understand the nature and complexity of the soil – environment relationships. Future use of the soil must take account of these relationships even in a society where we are increasingly able to manipulate our environment. As yet we know too little either of the nature of the soil – environment relationships or of the changes in these relationships and the response of the soil as the environmental conditions are changed. It is essential that this potential for change is acknowledged in any attempts to manipulate the soil – environment system.

2. Ecological and Political Aspects of Soil Protection

Herwig Hulpke

Soils are complex ecosystems that are strongly cross-linked to the other environmental compartments (water and air). Because of these linkages far reaching interactions with the other environmental compartments exist, through which soils have an important ecological mediator function. With respect to material transport processes, soils can be both sources and sinks.

In significant contrast to the other environmental compartments (air, water systems) humans took possession of soil from early times. The concept of “owned land”, which implies “possession of soil” underlines this fact. In some languages (e.g., German) land (Land) and soil (Boden) are often used as synonyms. Soil therefore represents the most important resource for human life in both its material and cultural aspects. Because soil is possessed as property, it has long been assumed that special care of the soil by the state could be dispensed with, since the soil's owners would already take care of it. This assumption may well be true in many cases for specific forms of use, such as agricultural use. But less care is felt when the utilization of the soil does not serve a single aim but several parallel or even conflicting purposes. Such multiple uses are typically the result of an increasing density of human population.

Soil is utilized by exploiting its functions. The great importance of soils for the existence of humankind is clearly suggested by the term “culture”, which is derived from the Latin word “colere” (to till).

The exploitation of certain soil functions does not only create benefits but can also cause damage. There are many examples for such conflicts. Agricultural use as opposed to planned use for housing or industrialization is a typical conflict of this type.

In the course of this, the use of the soil for nature conservation purposes or as a groundwater reservoir for the production of drinking water can be restricted or even endangered. Often, however, with cross-linked and complex ecosystems the conflicting interactions are more complicated and often neither transparent nor easy to understand. Nevertheless, when exploiting the soil it must always be borne in mind that the benefit from the use of one function can at the same time be detrimental to the use of another function. Soil protection is therefore chiefly a task whereby the utilization of soil functions has to be prudently selected. The properly targeted management of these uses must then be carried out in such a way that no unreasonable and unaccepted conflicts of the various intended uses will occur. At the same time the kind of use and its extent must also be taken into account. The understanding of soil protection as the management of competing claims for use by human beings is undoubtedly an anthropocentric view. But criticism raised against this view frequently fails to understand that this approach to action implies a large number of optional actions that can extend from the utilization of one or a few soil functions to the use of all conceivable or available functions. In the limiting case the utilization of any soil function can be entirely dispensed with. The use can therefore admit the range from “no functions” to “all.” As a result of this, and despite the anthropocentric approach, even extensive ecological requirements are taken into account. A system designed for the protection of soil functions consequently offers starting points for practicable as well as ecologically demanding measures.

With regard to its utilization and exploitation, the soil is the memory and archive of these actions. In this respect, pollutions arising from earlier uses (contaminated sites) play an important part in soil protection. As a result of the exploitation of soils in the past, restrictions often arise today on the utilization of some or all soil functions. Thus a soil that functions as a reservoir for groundwater regeneration and was contaminated in the past cannot be used as a water protection zone if through this contamination, owing to displacement processes, concentrations of contaminants appear in the groundwater making it unacceptable for drinking water catchment. The problem of exploitations in the past (contaminated sites) for soil protection is that the actual results of this exploitation often cannot be undone. Care must then be taken that this exploitation in the past has no harmful effects for present-day or future uses. The selection of appropriate uses therefore plays an important part. The precautionary principle, generally important in environmental protection, cannot apply here since, understandably, actions in the past cannot be cancelled by means of precautionary measures.

In the case of contaminated sites, the protection of soil functions can therefore not be managed by applying the precautionary principle. Instead, it must be orientated to the reduction or elimination of risks to soil functions intended for future utilization.

3. Function and Utilization of Soil

Claus G. Bannick, Konstantin Terytze, Gerhard Knoop, Michael Bredemeier, Hubert Schulte-Bisping

3.1. Soil Ecosystems

3.1.1. *Introduction*

Pedogenesis — the formation of soil — involves interactions between the lithosphere, hydrosphere, atmosphere, and biosphere (Fig. 1) [1]. At the earth's surface, the lithosphere becomes the pedosphere under the influence of weathering forces and organisms.

Figure 1. The soil in terms of the interaction of various spheres [1]

Thus soil is a complex, multiphase mixture of minerals, water, air, and organisms, together with products of their transformation and degradation. Depending on the climatic conditions and the nature of the underlying rocks, widely differing types of soil can be formed, whereby the rate of formation depends on how fast the rocks are weathered in the lower layers and on how rapidly biomass is degraded in the upper layers.

Lithosphere. The lithosphere is the rock mantle of the continents and the earth's surface beneath the oceans. The soil — the upper, inhabited part of the earth's crust — is formed from rocks by weathering, mineralization, decomposition, humification, texture formation, and displacement, under certain conditions (e.g., climate, leaf fall from vegetation). Weathering is the chemical, physical, and biological transformation of inorganic material such as basalt, granite, gneiss, carbonate, loess, and sand at the earth's surface by size reduction, degradation, transformation, and dissolution. With progressing soil development, the petrogenic starting materials are increasingly replaced by pedogenic materials such as clay minerals, which are more stable at the earth's surface.

Nine groups of minerals can be distinguished on the basis of chemical composition [2]:

Class I	Elements: metals (Ag, Au, . . .), metalloids (As, Sb, . . .), nonmetals (C, Se, . . .)
Class II	Sulfides: galena (PbS), sphalerite (ZnS)
Class III	Halides: halite (NaCl), sylvinite (KCl)
Class IV	Oxides, hydroxides: corundum (Al_2O_3), quartz (SiO_2), hematite (Fe_2O_3)
Class V	Carbonates, nitrates, borates: calcite ($CaCO_3$)
Class VI	Sulfates, chromates, molybdenates, tungstates: baryte ($BaSO_4$)
Class VII	Phosphates, arsenates, vanadates: apatite [$Ca_5[(F, Cl; OH)/(PO_4)_3]$]
Class VIII	Silicates: quartz (SiO_2)
Class IX	Organic compounds

As a result of the various soil-forming factors, characteristic horizontal layers, known as horizons, are formed, which differ in their biological, chemical, and physical properties. At the soil surface, the horizons contain larger proportions of organic material (O/A horizons), whereas the mineral component increases with increasing depth.

The horizons together make up the solum. The vertical distribution of the horizons in a two-dimensional cross section through the soil (soil profile) is the main criterion for classification of soils.

The smallest, undividable unit of a soil body is known as a pedon. Neighboring peda of the same soil type form a polypedon. The properties of the peda of a polypedon vary only slightly (e.g., horizon depth). On a larger scale, polypeda may be collected together as pedocomplexes.

Atmosphere and Hydrosphere. The spacial arrangement of the voids, the pore system, and the solid soil components determines the soil structure. The structures are classified in two main categories: primary structures and secondary structures (aggregates). In primary structures, aggregation is not apparent, due to uniform binding forces between the primary particles. Only in coherent structures are the primary particles permanently attached, forming a nonorganized mass, as in humus and clay soils. In secondary structures, primary particles are bound to one another far more strongly than to neighboring groups, thus forming secondary particles. Aggregates such as crumbs (1 – 10 mm) are formed by aggregation of individual grains. Segregates form by shrinkage from a coherent bulk. Interparticle binding can be by pure adhesion, or by cementation by mineral precipitates, inorganic colloids, roots, fungal hyphae, or bacterial slime. The soil solid phase can be separated into various particle sizes by classification processes such as sieving and sedimentation. The mass composition of the solid phase as a function of particle size is known as granularity or texture. Particles >2 mm make up the coarse fragment, and those <2 mm, the fine earth, which is subdivided into sand (63 – 2000 µm), silt (2 – 63 µm), and clay (<2 µm) fractions.

Soil pores are also classified according to size: large pores (>50 µm), medium pores (0.2 –50 µm), and fine pores (<0.2 µm). Large pores bind soil water only weakly and are easily drained. Medium pores can be penetrated by root hairs and microorganisms and store capillary water available to plants. Fine pores bind water so strongly that it is no longer available to plants. The soil contains a pore system formed by mineral particles generated by weathering. The two main types of particle packing (see Fig. 2), cubic loose and hexagonal close packed, influence various soil processes.

Figure 2. Packing of spherical particles [3]

Biosphere. The totality of the ecosystems of the earth's crust, in close interaction with the hydro-, litho-, and atmospheres, makes up the biosphere. The total organic fraction of the solid phase of the soil is divided into biomass, which includes all living organisms (soil flora and fauna), and the necromass, which contains all dead organisms and their transformation products. The latter category is derived from both underground (e.g., roots) and overground sources (e.g., leaf fall). The degradation products of the necromass are the humic substances which, depending on their solubility, are divided into the alkali-insoluble humins and the alkali-soluble humic acid precursors and humic acids (see Section Regulating Functions).

Within their biotope, the soil organisms form a community known as an edaphon. The edaphon is divided according to the size and way of life of the organisms. In the division according to morphological size [4] the edaphon is divided into microflora (bacteria, fungi, algae), microfauna (protozoa), mesofauna (nematoda, rotifera, tardigradae, mites, and collembola), macrofauna (annelids, snails, insects and their larvae), and megafauna (vertebrates); see Figure 3.

Figure 3. Classification of soil organisms by size [4]

The particular living conditions in the soil are coupled with typical modes of behavior of the organisms. Thus the group of soil burrowers (fodient edaphon) is formed mainly of organisms from the mega- and macrofauna (annelids, insects and their larvae) which generate their own living environment by burrowing and agitation of the soil. Serpentine edaphon move through the pores of the soil (rhizopods, annelids, collembola). They are restricted to open, air-containing pores and are found mainly in the upper soil layers. The soil swimmers (natant edaphon) are adapted to life in the water of the soil. They include some microflora and the majority of the mesofauna (rotifera, nematodes, tardigradae). Bacteria and fungi, which rapidly cover the walls of pores or enter soil voids belong to the sessile edaphon [5].

The soil flora and fauna introduce organic material into the soil system. Almost 100 % of the elemental composition is accounted for by C, O, H, N, and S. The central importance of the soil is due to the fact that fundamental ecological processes interact there. Thus the soil is an essential basis for all life processes. Soil functions are summarized in Figure 4.

Figure 4. Soil functions

From the environmental viewpoint, the most important functions are the regulating and productive functions, known together as ecological soil functions. Other soil functions include raw material resources, land for building, recreational areas, and waste disposal.

The filter function is the mechanical retention of particules and colloids by the soil-pore system.

The buffer function includes the binding of dissolved substances by absorption and desorption, the inclusion and release of substances (including water) by pore spaces, and the in- and excorporation of substances by soil organisms. The habitat function is the ability of the soil to support colonies of organisms within and upon the soil. This includes the function of the soil as substrate for higher plants.

The productive function differs from the habitat function in that here the economic exploitation of the biomass is of primary importance.

The other soil functions are mainly or exclusively of anthropogenic nature. Here, the ecological functions are of minor importance compared to the anthropogenic exploitation or are indirectly exploited, for example, in the degradation or sorption of pollutants. In contrast to the other soil functions (raw material deposits, building, recreation, waste disposal), the regulatory and habitat functions can be defined solely on the basis of the natural pedological and ecological properties of the soil, regardless of the use to which it is put. The productive function can be distinguished on the basis of both ecological aspects (habitat for cultivated plants) and socio-economic criteria, since it is directly interlinked with agriculture and forestry.

3.1.2. *Ecological Soil Functions*

3.1.2.1. *Regulating Functions*

The regulating function of the soil depends on the regulation of natural material and energy cycles. It includes all material and nonmaterial introductions to the soil and the process therein which they initiate.

Filter Function. Filtration is defined as mechanical retention of material >100 nm in size [6]. Filtration occurs during the flow of aqueous suspension, through the pore systems.

The behavior of the soil water (hydraulic potential ϕ) is determined by the gravitation potential z (downwards) and the matrix potential Ψ (upwards). At equilibrium, these two potentials are equal, i.e., $\phi = (-\Psi) + (+z) = 0$. Addition of water (e.g., by precipitation) increases the matrix potential and displaces the equilibrium. This infiltration (⟶ Ecology and Ecotoxicology) is one of the most important effects counteracting erosion.

Decreased filter performance can arise through pore blockage due, for example, to compaction or clogging with mud. Pore blockage can also have deleterious effects on the transformation and habitat functions (stagnant water, air deficiency).

Buffer Function. The buffer function encompasses the following major areas:

1. Buffering of water balance
2. Buffering of acid inputs
3. Buffering of nutrients and pollutants

The buffering of water balance is largely a result of the ability of soils to store water in pore spaces by means of capillary forces. Since the pressure of a liquid (tension) is lower than atmospheric pressure, the liquid rises in a capillary until hydrostatic equilibrium is attained. The capillary pressure and hence the height to which the liquid rises increase with decreasing capillary diameter.

The water-storage capacity of a soil is characterized by the amount of water that can be retained for a given value of capillary pressure (pF characteristic). The pF value is defined as the logarithm of the negative capillary force ($-\Psi$), or the pressure in centimeters water column. Of particular importance for the habitat and productive functions is water available to plants, with pF = 1.8 – 4.2 (exploitable field capacity). For each soil type, at a given pF value, the quantity of water that can be retained against the force of gravity can be determined. The exploitable field capacity (in mm/dm) for some substrates is given in the following [7]:

Fine sand	13
Silt	25
Sandy loam	19
Clay	15

Buffering of acid inputs is achieved by various soil buffer systems, depending on the pH range:

Neutral (6.2 – 8.0)	carbon dioxide/ carbonate buffer
Acidic (4.2 – 6.2)	exchange buffer
Highly acidic (2.8 – 4.2)	aluminum buffer

Buffer systems consist of a weak acid or base and the corresponding salts, and maintain constant pH within a certain range. All soils are exposed to acids, both of natural (e.g., absorption of nutrient ions by plants with release of protons) and anthropogenic origin (e.g., fertilization, atmogenic inputs).

Carbonate-containing soils can buffer protons by formation of hydrogencarbonate

$$CaCO_3 + H^+ \rightleftharpoons Ca^{2+} + HCO_3^-$$

After exhaustion of the carbonate buffer, buffering is performed by the exchange buffer system, whereby all cations of the mineral and organic ion exchangers are replaced by protons. Below pH 4.2 in the aluminum buffer system, destruction of the crystal lattice structure and release of aluminum ions occurs

$$AlO(OH) \cdot H_2O + 3H^+ \rightarrow Al^{3+} + 3H_2O$$

The buffering of nutrients and pollutants affects most ecological soil functions. It is made possible by the presence of organic and inorganic exchangers, whereby the following adsorption phenomena can occur:

1. Van der Waals forces: relevant for organic pollutants, humus
2. Hydrogen bonds: relevant for organic pollutants, mineral surfaces
3. Electron donor – acceptor complexes: relevant for organic pollutants, humus
4. Hydrophobic bonding: relevant for organic pollutants, humus
5. Ion bonding: relevant for organic pollutants, inorganic pollutants and nutrients, humus, clay minerals
6. Covalent bonding: relevant for organic and inorganic pollutants

For nutrients and inorganic pollutants, ion formation is the most important process. Ion exchangers have positive or negative excess charge, thus binding anions or cations. Sorption of this type is reversible and an ion-concentration-dependent equilibrium is established in the soil solution. The sorption strength depends on the distance between the bonding partners, which is largely determined by their hydration shells, decreasing with increasing distance according to the Coulomb law $P \sim Q_1Q_2/r^2$.

In addition, the strength of sorption increases with increasing ion charge, which is taken into account in the Hofmeister ion series of decreasing hydration shell and increasing exchange potential:

$$Li^+ < Na^+ < k^+ < Rb^+ < Cs^+$$

$$Mg^{2+} < Ca^{2+} < Sr^{2+} < Ba^{2+}$$

The input of nutrients and inorganic pollutants into the soil, their dissolution in soil water, buffering by adsorption and desorption, uptake by plants, and loss of eluates can be depicted in nutrient and pollutant cycles (⟶ Ecology and Ecotoxicology – Nutrient Cycles and Productivity of Terrestrial and Aquatic Ecosystems). The ecological cycle for heavy metals is shown in Figure 5.

Figure 5. Heavy-metal cycle in the ecosystem [8]

[a] Can be used as indicator for accumulation. [b] Potentially biorelevant. [c] Momentary biorelevant increase of metal concentration in the dissolved phase as indicator for biotoxicity and bioacumulation.

Heavy metals can be bound in the soil in the following ways (R represents a solid/dissolved inorganic/organic compound, e.g., iron oxide, clay mineral, humic substance):

Solid state

Unspecifically adsorbed, e.g., $R\langle^{O}_{OCd^{2+}}$ (aq.)

Specifically adsorbed, e.g., $R-OCu^{+}$

Metal salts, e.g., $PbCO_3$, $Pb_3(PO_4)_2$, PbS

Oxides, e.g., As_2O_3

Bound in silicates e.g., tin in Hornblende

Dissolved

Aquo complexes, e.g., $Cd^{2+}_{(aq.)}$, $Pb^{2+}_{(aq.)}$

Inorganic complexes, e.g., AsO_4^{3+}, $Zn(OH)_3^{-}$, $Pb(CO_3)_2^{2-}$, $CdCl^{+}$

Organic complexes and chelates, e.g., $CH_3Hg^{+}_{(aq.)}$, R–Cu–R

The pollutant content of the soil is characterized by background values, which are representative values for the general background content of a substance or group of substances in the soil. When statistically determined they can be used to give the local, regional, or nationwide pollution of the soil. Table 1 lists values based on the evaluation of over 16 000 soil samples collected nationwide in Germany [9-11]. The samples were collected by a uniform method, and the 50th and 90th percentiles of the heavy-metal content determined for three types of land usage. The shown values are representative for the rural area.

Table 1. Heavy-metal contents in rural areas for arable land (90th percentile)

Substrate	As	Cd	Cr	Cu	Hg	Ni	Pb	Sb	Zn
Sand	3.0	<0.3		3.0	0.03	<3.0	13	<0.3	14
Sandstone	7.0	0.9		15	0.11	30	75	0.6	43
Loess	9.6	<0.3	149	25	0.16	44	51	1.1	89
Boulder clay	5.4	<0.3		14	0.08	19	32	0.9	76
Marshes									
Claystone	10	1.1		27	0.14	74	61	0.6	121
Limestone									
Basalt	5.0	0.8		71	0.1	339	49		168

Soil has to fulfill a buffer function to protect humans, plants, and groundwater from soil pollutants. Soil pollutants and the corresponding pathways are listed in Table 2.

Table 2. Priorities of relevant soil pollutants

Relevant pollutants in the pathway		
Soil–human	Soil–plant	Soil–groundwater
Arsenic	arsenic	heavy metals
Lead	lead	crop-protection agents
Cadmium	cadmium	volatile chlorinated hydrocarbons
Chromium	chromium	
Nickel	copper	
Mercury	mercury	
Vanadium	thallium	
Zinc	zinc	
Benzo[*a*]pyrene	aldrin/dieldrin	
Benzene	benzo[*a*]pyrene	
DDT (total)	endrin	
Dieldrin	hexachlorobenzene	
PCB (total)	pentachlorophenole	
PCDD/PCDF*	DDT (total)	
Phthalates	nitrate	
1,1-Dichloroethane	PCDD/PCDF*	
Dichloromethane		
Tetrachloroethylene		
Toluene		
Trichloromethane		
Xylene		
Vinylchloride		
Cyanides		

* PCDD = polychlorinated dibenzodioxins; PCDF = polychlorinated dibenzofurans.

Transformation Function. The behavior of chemical compounds in the pedosphere depends on the properties of the substance, the location, and in some cases is affected by anthropogenic activities. The transformation function provides for self-cleaning of the soil. Degradation and transformation of substance in soil can occur abiotically (e.g., reactions on mineral surfaces, photochemical reactions) or biotically. One of the most important forces of the self-cleaning capacity of soils are the microorganisms, which provide the enzymes necessary for biotic transformation processes. Microorganisms use substances that enter the soil as nutrients or energy sources, whose exploitability increases with decreasing persistence of the compounds. After a substance has entered the soil, the microflora require a latent period (lag phase) for the development of the specific species spectrum required for its metabolization. This time period depends on the xenobiotic properties of the substance. If the substance is introduced more often, the lag phase becomes shorter and the persistence decreases. In addition, all processes that stimulate microbial activity in the soil are suitable for increasing its metabolic potency. These include application of organic and inorganic nutrients and cultivation of the soil.

The degradation and transformation of postmortal plant and animal material to humic substance is also attributed to the transformation function. Humic substances are naturally occurring biogenic substances with characteristic yellow to black color, high particle density, and persistence. Humic substances have been found in materials that have undergone coalification, such as peat, liquites, and lignites. The humic substances can be classified according to their solubility. Humic substance fractions and their solubility, as determined by various authors, are as follows:

1. Classification according to SCHEFFER, ULRICH [12] :

Crenic acids	acids, alkali, water, alcohol
Apocrenic acids	acids, alkali, water, alcohol
Hymatomelanic acids	alkali, alcohol, acid (partially)

Gray humic acids	alkali
Brown humic acids	alkali

2. Classification according to FLAIG [13] :

Fulvic acids	acids, alkali
Hymatomelanic acids	alkali, alcohol
Humic acids	alkali
Humines	insoluble

3. Classification according to SWIFT [14] :

Fulvic Acids	acids and alkali
Humic acids	alkali
Humines	insoluble

In contrast, ZIECHMANN [15] classifies the humic acid fractions according to their reactivity and their ability to undergo further humification with uptake of oxygen:

Starting materials (nonhumic)	organic substances undergoing humification lightly colored to colorless
Humic acid	reactive fraction, gradually transforming into humic acid light brown to brown
Humic acids	fraction containing carboxylic acid groups, phenolic OH group base-soluble, precipitate in acid intense brown color
Humines	inactive fraction insoluble intense brown color

The principle route for the formation of humic substances is shown in Figure 6. In reality, the formation mechanism presented here may be far more complex. This is due firstly to the wide variety of substance groups that can be involved in the humification process, and secondly to the activities of the micro- and macrofauna, which are responsible not only for producing these substances but also for mineralization, which competes with humification. Substances produced by microorganisms during the degradation of organic matter, as well as partially degraded, but considerably modified, substances, are involved in the humification process. In contrast to this incorporation of degraded biopolymers in a preexisting humic substance system, it is now being discussed whether such degraded biopolymers should themselves be designated as humic acids.

Figure 6. Formation of humic substances [15]

HAP = humic acid precursors; HA = humic acid; Hm = humines

Degradation and transformation of nutrients (⟶ Ecology and Ecotoxicology – Nutrient Cycles and Productivity of Terrestrial and Aquatic Ecosystems) is another important transformation process in soils and also involves microorganisms. Of major importance for the cleansing of the soil is the degradation and transformation of pollutants. The microbial degradation of various groups of chemical substances with ultimate mineralization is a first-order reaction. This has been shown, among others, for some chlorinated hydrocarbons, triazine derivatives, organic phosphorus compounds, carbamates, thiocarbamates, thiurams, urea derivatives. Under comparable conditions, the rate of microbial degradation is given approximately by

$$c = e^{-kt}$$

where *c* is the concentration of the compounds, *t* is time, and *k* is the mineralization rate.

Plotting log *c* against *t* gives a straight line whose gradient is the mineralization rate *k*, which allows predictions of the persistence of the compound under given soil and other environmental conditions to be made. Strongly sorbent, dry, low-nutrient soils with relatively low microbial activity exhibit small gradients, whereas soils in which the nutrient supply, air and water balance and hence the microbial activity are optimal give a steep gradient.

Continuation of the microbial transformation process in the soil is essential for plant growth and hence for the existence of animals and humans. In this context, the question of whether the increasing production of chemicals in the last few decades, which has led to intentional or accidental introduction of intermediate, final, and waste products into the soil, can seriously affect the biological functions of the soil, is becoming of increasing importance.

To investigate this, it is necessary to study the behavior of numerous chemical substances in the soil and to elucidate their effects on soil organisms. Depending on their properties, chemical pollutants can persist in the soil or be degraded. Thus a distinction can be made between persistent and nonpersistent pollutants. Both groups can affect soil microorganisms and their activity in various ways (Fig. 7). Persistent pollutants accumulate in the soil, acting on the soil microflora either alone or as complexes with clay minerals, humic acids, and oxides. Nonpersistent pollutants undergo a decrease in concentration due to chemical or physicochemical, but mainly biological/biochemical processes. If such processes result in mineralization of the pollutant, a detrimental effect on soil microorganisms is unlikely. However, since complete mineralization is generally the exception, it can be expected in many cases that intermediate degradation products or the final products of transformation reactions could adversely affect the soil microorganisms and their activity. Such effects can change the condition of the total biomass as well as the species composition of the microorganism population and its mineralization and synthesis activity.

Figure 7. Behavior of pollutants in the soil and their interaction with microorganisms [16]

3.1.2.2. *Habitat Function for Organisms in and upon the Soil*

The organic material of the soil consists of 85 % postmortal substance, 10 % plant roots, 4 % bacteria and fungi, and 1 % soil fauna.

Figure 8 shows the soil microorganisms and their important ecological functions.

Figure 8. Soil microorganisms and their ecological functions

Bacteria and fungi account for 90 % of degradation, while soil animals are responsible for only ca. 10 %. However, soil animals are highly effective in accelerating microbial degradation and can increase the availability of nutrients by up to 50 %. Field studies have shown that decreasing their numbers decreases the degradation performance of the soil by up to 40 %. In general, single-cell organisms, worms, and anthropods each make up one-third of the soil biomass. The number of organisms per square meter in the upper 30 cm of the soil is as follows [17]:

Bacteria

	60×10^{12}
Fungi	10^9
Algae	10^6
Single-cell organisms	500×10^6
Threadworms	10×10^6
Mites	150 000
Collembola	100 000
White ringworms	25 000
Earthworms	200
Snails	50
Spiders	50
Isopods	50
Millipedes	150
Centipedes	50
Beetles	100
Fly larvae	200
Vertebrates	0.001

Respiration of an organism is a measure of its metabolic activity and, therefore, its material turnover. Protozoa account for 70 % of respiration — considerably higher than their biomass fraction of about one-third. It is not general knowledge that these soil-inhabiting microfauna produce approximately as much biomass as earthworms. In the food chain, protozoa represent an ecologically important link between bacteria and small metazoans (e.g., rotifera and nematoda) and thus exhibit pronounced catalytic activity towards bacterial processes and remineralization processes in the soil.

Taxonomically, soil protozoans can be divided into three main groups: small flagellates of size 3 – 10 µm; 2 µm flat naked amoebas with diameter 10 – 300 µm and testate amoebas of size 20 – 200 µm; and ciliates (20 – 300 µm).

Their occurrence is mainly limited to the upper 10 cm of the soil. Due to their small size or flat, flexible form, flagellates and naked amoebas can enter even the smallest soil pores (≥ 2 µm). In terms of ecological function, biomass (Table 3), and distribution, the three groups of protozoans (flagellates, amoebas, and ciliates) can be regarded as being of equal importance.

Table 3. Distribution of "naked" protozoa in different soils and in the rhizosphere (numbers given: individuals/g dry matter [18] and, below, relative biomass fraction (%) calculated according to [19])

	Arable soil		Forest soil, subtropical	
	Uncultivated soil	**Rhizosphere**	**Soil (total)**	**Rhizosphere**
Flagellates	570 – 14 000	1600 – 65 000	22 000 – 3 127 000	4000 – 8 231 000
	4 – 16	8 – 15	19 – 58	12 – 16

	17 – 29	0 – 41	3 – 76	23 – 84

The broad-spectrum activity of pollutants in soils, in particular their effects on entire colonies of organisms, has remained largely unregarded, partly due to the lack of suitable test systems. Classical laboratory tests (e.g., LC_{50} values) are unsuitable for predicting the true toxicity in open country. To make more accurate predictions for both existing and new substances, current laboratory tests, which are restricted to a few selected animal species, generally on standardized substrates, must be extended to further soil animal species, and additional tests on organisms, organs, single cells, and cell compartments are also required. Novel test methods based on enzymes as biomarkers avoid the need for animal tests and can also be used at sublethal concentrations. Although such tests provide important ecological data on the lethal and sublethal action of pollutants, they are not suitable for predicting effects on species colonies in ecosystems. This information can only be obtained by means of field experiments designed to take into account temporal, spatial, and genetic population variations in the ecosystem and the varying bio-availability of pollutants from species to species.

3.1.3. *Productive Function*

The productive function is the ability of the soil to act as substrate for cultivated plants (food and feed plants, renewable resources). Effects on the productive function are generally assessed in economic terms, rather than ecologically, since cultivation in agriculture, forestry, and horticulture is intended to produce a profit. Nevertheless, a number of ecologic soil functions are affected by cultivation.

3.1.3.1. *Agriculture*

Plants obtain their nutrient elements, but also pollutants, mainly from the soil. The supply of nutrients is generally typical for the type of soil and region. However, in modern agriculture external measures are applied to increase the harvest: inorganic and organic crop-protection agents, organic and mineral fertilizers, and utilization of organic and mineral wastes, all of which can lead to pollution of the soil and can damage soil functions.

Crop-Protection Agents. The entry of CPA into the soil as a result of agriculture is a potential influence on soil function. The CPAs are designed to alter the balance of nature in favor of the cultivated plants.

The behavior of CPA in soil depends on their properties, the way in which they are used, and on local conditions. The soil determines important properties of the location, especially the hydrological properties.

The amount of CPA applied, the frequency of application, and the time at which it is applied are relevant to movement of the agents in the soil and their potential entry into water systems. The manner in which a CPA is used affects its degradation, which is faster at the higher temperatures of spring and summer and leads to a more rapid decrease in the amount of CPA present. In autumn and winter degradation is generally slower. However, general statements valid for all CPAs cannot be made.

Fertilization and Waste Utilization. Fertilization and the utilization of waste materials can lead to the introduction of both organic and inorganic pollutants into the soil. In contrast to the application of crop-protection agents, this is an unintentional contamination. The aim of fertilization, which can include utilization of waste, is to improve conditions for the growth of cultivated plants, either by direct action on the plants themselves or by effecting the soil. The macronutrients nitrogen, phosphorus, and potassium are the most important for the nutrition of cultivated plants. Thus in the sustainable development of agriculture, both nutrient and pollutant aspects must be taken into account.

Nutrient Aspect. The high productivity in countries of Central Europe, compared to average world harvests, is only attainable by intensive application of fertilizers. The concept of location-specific soil fertility formulated by KLAPP [20], who defined this as the soil's own level of natural, persistent performance which distinguishes it from other soils, is not applied in conventional agriculture. According to KLAPP the most important aspect is the sustainability: the long-term ability of the soil to provide all requirements for plants to flourish, that is, to provide constant or only slowly decreasing harvests without fertilization. In contrast, in modern agriculture, fertilization is regarded as guaranteeing the nutrient requirement of the plants, taking into account the nutrients already available in the soil. The natural productivity of the soil is thus completely disregarded. In modern agriculture, the target of fertilization to an extent appropriate to the requirements of the plants is not met. If a balance is determined for nitrogen, the result is a considerable fertilizer excess. The starting point for sustainable use of the soil should be a nutrient supply that is appropriate to the needs of the plants and which avoids an excess in the soil and release into other environmental compartments. Furthermore, in intensive agriculture, the proportion of nutrients introduced into organic materials should be restricted to 60 % of the total nitrogen requirement. The reference points for fertilization planning are the exploitable components in the following plant population, which increase with increasing frequency of utilization and the amount of organic material utilized (see Transformation Function.). Residual material remaining on the field after harvesting must also be included in the balance, and manure should be used in preference to external waste materials.

Pollutant Aspect. Mineral fertilizers, organic fertilizers, and wastes all introduce inorganic and organic pollutants into the soil and can cause adverse effects there and in other environmental compartments. Mineral fertilizers can contain various amounts of pollutants, depending on the origin of their raw materials and the production process used.

The main pollutants entering soils via fertilization are Cd and Cr, and to a lesser extent Pb, Ni, and As. The Mn, Cu, and Zn contents of fertilizers are, with the exception of the high Cu and Zn content of liquid pig manure, low, lying in the nutrient element/trace nutrient element range. Most of the heavy metal load comes from phosphate rock and P fertilizers derived therefrom (super and triple phosphate, partially digested and soft phosphate rock), Thomas phosphates, and phosphate-containing multinutrient fertilizers. P fertilizers derived from phosphate rock can exhibit high Cd contents, depending on the origin of the phosphate rock. Thomas phosphates have high Cr contents, resulting from the production process. The specific quantity of heavy metals introduced is strongly influenced by the various land-use and fertilization systems. According to BOYSEN [21], the Cd entry is up to 4.1 g/ha in

conventional farming, up to 4.8 g/ha for meadowland, but only 0.9 g/ha for ecological agriculture. Data on organic pollutants in fertilizers are not yet available in sufficient quantity. In terms of quantity, the most important organic fertilizers are liquid manure, sewage sludge, and compost.

In Europe only sewage sludge is subject to EC regulations which set values for heavy metals in sewage sludge and soil. In addition, the methods of application are specified, allowing theoretical permissible pollutant loads to be calculated. For compost, numerous quality marks exist, whereby the pollutant concentration is specified. They do not, however, set limits on quantity. If an average application of 10 t ha^{-1} a^{-1} is assumed, a cadmium load of 10 – 40 g/ha can be calculated [22].

However, depending on the region and the spectrum of discharge or compost starting materials, these theoretical pollutant loads are not always fully exploited.

The inputs can be compared to theoretical outputs, as exemplified below for the Cd and Hg balance. For the average German wheat harvest of 5 t ha^{-1} a^{-1} and a tolerable Cd content of 0.2 mg Cd/kg dry matter wheat (marketability criterion), a potential output of ca. 1 g ha^{-1} a^{-1} results. The Hg output is 0.3 g ha^{-1} a^{-1} (0.06 mg Hg/kg dry matter).

If the values specified e.g., by the Drinking Water Regulations (Trinkwasserverordnung), are taken as the tolerable pollution of the leachate, then for the average leachate quantity in Germany of 200 mm/a (2×10^6 L ha^{-1} a^{-1}), a potential Cd output of 10 g ha^{-1} a^{-1} and an Hg output of 2 g ha^{-1} a^{-1} result. Thus the potential outputs are already met by the potential inputs from the utilization of waste materials alone.

3.1.3.2. *Forestry*

After agriculture, forestry is the second largest use of land. In forestry, atmospheric nutrients and pollutants are of major importance.

The problem of pollution in forestry is exemplified by a comparison between Cd inputs and outputs (in g ha^{-1} a^{-1}) for a forest soil (spruce trees, ca. 120 years old) in a mountainous region of northwest Germany [23]:

Total input	6
Precipitation	2.7
Interception	3.3
Total output	15.3
Leachate	13.5
Crop (trunk wood without bark)	1.8

Thus the mean annual output is 2.5 times higher than the atmospheric input by precipitation and dry deposition. It is questionable whether the limit values of the German drinking water regulations are suitable quality standards for assessing outputs in the leachate. For a limit value of 0.005 mg Cd/L water, a leachate flow of 424 mm/a, and given the requirement that the leachate water quality must comply with the drinking water regulations, a tolerable Cd output of 21.2 g ha^{-1} a^{-1} can be calculated. This is considerably higher than the actual leachate output of 13.5 g ha^{-1} a^{-1}. In analogy to the specified quality target that the output should not exceed the input, according to this model calculation, an additional Cd input of 9.3 g ha^{-1} a^{-1} would be possible without exceeding limit values specified for drinking water.

The fact that for the material balance for cadmium in this example, the output is more than twice as high as the input shows that this soil has already lost its function as a filter medium for the formation of new groundwater. The mobilization of cadmium accumulated in the forest soil as a result of acidification demonstrates the problems that arise when the filter capacity of the soil is exhausted. The filtration capability of the soil can only be regarded as undisturbed if the output (at the background level) is lower than the current input. If changes in soil properties lead to release of accumulated materials, then pollution of the groundwater or of the habitat for organisms cannot be excluded.

3.1.4. ***Other Soil Functions***

3.1.4.1. *Utilization of Wastes*

The exploitation of waste is possible in cases where it is both safe and useful. Benefits to the soil occur if at least one soil function is improved without permanent detriment to other natural soil functions or other environmental compartments. In the use of organic wastes in agriculture, the benefits can be assessed in terms of the fertilizer effect. Utilization of waste should be safe with regard to nutrients and pollutants. An important part of the recycling and waste business in Europe is the material utilization of waste with an increasing pressure to use wastes in soil-related applications.

In Germany for example, the distinction between mineral and organic wastes is defined in the regulation TA Siedlungsabfall, which excludes wastes containing >5 % TOC (organic wastes) from dumps to minimize the pollution of the leachate associated with the degradation of organic materials.

Soils should be included under mineral wastes because the organic matter (up to 30 %) they contain differs strongly from organic wastes in type and constitution. They therefore represent a special case. Organic wastes are used in agriculture, gardening, and landscaping, whereby a distinction can be made between repeated application, mainly in agriculture, and one-time use, mainly in recultivation and landscaping. Mineral wastes are mainly used in landscaping and in recultivation and building projects; smaller amounts are utilized in agriculture. An exception is soil material, which is used in considerable amounts for improving soil functions.

An important criterion for assessing the harmlessness of such measures are the background concentrations of pollutants (see Section Regulating Functions), which should not be exceeded by the input pollutant load of organic wastes. In the utilization of organic wastes, the pollutant load is the most important factor, since they remain almost entirely on the surface after mineralization of the organic component, contributing to an increase in the pollutant potential.

In the case of mineral wastes, there is generally no loss of mass after use in the soil, so that a different pollution assessment concept must be used.

The pollutant concentrations in the waste should not exceed the background concentrations in the location of use. If the values are compatible, application is possible, since a deterioration in soil quality with respect to pollutant concentration will not occur. For the application of mineral wastes that exceed the background values, eluate investigations must be undertaken, which indicate whether risks to groundwater quality are present.

The use of soil material in the topsoil region is subject to strict requirements for the soil properties. This is due to the requirements of plants for water retention capacity, aeration, rootability, warmability, and nutrient storage capacity. For this reason, the soil should have similar composition and properties to that at the site of use. Poorer soil materials should not be applied to soils of higher quality.

3.1.4.2. *Raw Material Deposits*

Soils that act as raw material deposits include sands for building and clays for ceramic production, but the largest areas are taken up by lignite mining. Other areas that generally require recultivation are the slagheaps from salt, ore, and coal mining dumps and military training areas. All of these lack a plant-supporting upper layer and have lost the natural soil functions.

Table 4 compares the three main lignite mining areas in Germany.

Table 4. Breakdown of areas under mining law [24]

	Lignite mining districts, ha		
	Rhenish	Central German	Lausatia
Total area used	24 500	46 900	48 999
Area subjected to recultivation	15 600	22 000	24 655
Operated area	8 900	24 900	24 344

Especially in the former German Democratic Republic, there are a large number of areas still to be recultivated. In the Land Brandenburg alone, as of 1994, the total area affected by open-cast mining of lignite was 50 000 ha. About half of this has so far been rendered reusable. The recultivation of devastated and mined areas is intended to restore or improve the natural soil function. This includes building up a plant-bearing soil layer in sufficient quality and depth. Other targets are:

1. Increasing the content of organic substances in the topsoil
2. Introduction of plant nutrients
3. Regulation of the pH value
4. Stimulation of soil life

At the same time, deterioration of soil function due to pollution input, addition of inappropriate nutrients, and compaction must be avoided.

3.2. Land Utilization and Soil Destruction (Statistics)

3.2.1. *Introduction*

The consumption and destruction of soils, i.e., the destruction of the surface soil or of the topsoil [25], is one of the biggest ecological problems of the world. The soil is the basis for food production and will remain so in future [26]. While in the highly developed and industrialized countries problems of soil acidification and of contaminated sites (see Section Effects of Abandoned Waste Disposal Sites) are discussed [27], [28], soil erosion (Section Erosion), soil salination, and desertification in other parts of the earth progress unabatedly.

Many thousands of hectares of cultivated land are lost each year through erosion, salination, and desertification. Thus, in 1975 the soil of half of the Indian subcontinent, 150×10^6 ha, was seriously affected. In the United States in 1975, erosion had made nearly 40×10^6 ha unusable for agricultural cultivation [26]. In Argentina in 1980, 22×10^6 ha, nearly 16 % of the cultivated land, had been destroyed by wind erosion. In the 1970s – 1990s, according to estimates, the farmers lost 480×10^9 t of topsoil, which equals the entire topsoil of India [29]. These few examples should prove the seriousness of the problem of soil destruction.

3.2.2. *Land Utilization*

Table 5 shows a breakdown by continents with regard to the land area and its use [30].

Table 5. Land area and use (in 10^6 ha; source [30])

	Land area	Arable land incl. permanent crops	Permanent pasture	Forest
Africa	2963	211	900	650
North and Central America	2144	272	349	549
South America	1753	127	516	886
Asia	3098	573	1110	548
Europe	2260	304	183	1039
Oceania	849	54	413	198
World	**13 067**	**1541**	**3472**	**3870**

In the following, the land utilization and land use are considered in more detail for the Federal Republic of Germany, as an example of an industrialized country. Figure 9 shows the land use distribution in the Federal Republic of Germany in 1994. Settlement and traffic areas, which are composed of residential and office buildings, industrial facilities, administrative and educational establishments, as well as roads, sports fields and airfields, cemeteries and parks, in 1994 occupied about 12 % [31]. For comparison, in 1950, the proportion of residential, industrial, and traffic land was 7.2 %. Figure 10 [32] shows the daily change in the years 1981 to 1985.

Figure 9. Land use in the Federal Republic of Germany (source: [31])

Figure 10. Daily change in land use from 1981 to 1985 in hectares (source: [32])

The settlement area in Germany increases by ca. 105 ha daily [33].

3.2.3. *Soil Destruction*

Proceeding on another scale than the sealing of land mentioned above are the destruction of soil by erosion, salination, desertification, and destruction of forests.

In the frequently very labile ecosystems in the non-industrialized countries, where 80 % of the world population growth occurs, industrial methods of agriculture lead much more quickly to the destruction of the valuable topsoil. In the subtropics and tropics, this leads rapidly, because of erosion, to the expansion of dry areas and desertification after a short phase of meager yields [34].

Erosion. Erosion by wind or water plays the most important part in soil destruction. Worldwide, $25\,000\times10^6$ t of soil are washed away by water erosion every year [38]. The extent of erosion is shown in Tables 7 and 6.

Table 6. Estimates of global rates of soil erosion and likely future trends (source [39])

Region	Soil erosion by water				Soil erosion by wind	
	Area, 10^6 ha	Denudation rate[2], mm/a	Dissolved load, 10^6 t/a	Future trends[*]	Area, 10^6 ha	Future trends[*]
Africa	227	0.023	201	+	186	+

[*] + = Increased risks; – = decreased risks;
[**] total value for Central America and North America

Chinese soil scientists estimate that in their country since the 1960s almost 10 % of the arable land has been lost through erosion and desertification [40]. In the United States in the last 200 years about one-third of the surface soil has been destroyed by erosion [41].

At the 7th Conference of the International Soil Conservation Organization in 1992 in Sydney, the following figures were reported by the project for the worldwide estimation of soil degradation: Between the 57th degree of latitude South and the 72nd degree of latitude North, 164×10^6 ha, i.e., 15 % of the earth's surface, show more or less strong signs of degradation. In addition, 295×10^6 ha, corresponding approximately to the size of India, have to be classed as highly degraded. About 124×10^6 ha of these are in African and 106×10^6 ha in Asian countries [35].

Chemical Degradation. The agricultural lands rendered usable by artificial irrigation are threatened, after some time of use, by salination. Table 7 shows the significant proportion of soil areas degraded by salination [35-37].

Two further aspects of chemical degradation, i.e., contamination and acidification of soils, are closely related to anthropogenic industrial pollution. While their total extent is relatively small compared to the areas influenced by the other chemical degradation processes, there are numerous “hot spots” with severe problems in the heavily industrialized regions.

With respect to area, loss of nutrients is the most important chemical degradation process. Nutrient losses result from current or historical overexploitation of soils by non-sustainable cultivation methods.

Table 7. Extent of human-induced soil degradation for the main types of soil degradation (10^6 ha, source [37])

Types of degradation	Light	Moderate	Strong/extreme	Total

Water erosion	343	527	224	1094
Wind erosion	269	254	26	549
Chemical degradation	93	103	43	239
Loss of nutrients	52	63	20	135
Salinization	35	20	21	76
Contamination	4	17	1	22
Acidification	2	3	1	6
Physical degradation	44	27	12	83
Total	**749**	**911**	**305**	**1965**

Desertification. About 25 % of the earth's surface is subject to the spread of deserts and every sixth human being is affected [42]. Every year, about 6×10^6 ha of pastureland become desert [43]. The deserts have in this way expanded by 120×10^6 ha from 1970 to 1990. This corresponds to a greater land area than is cultivated in China today [47].

In the late 1970s the United Nations estimated the risk that non-desert land will become desert as follows:

50 % desertification of non-desert land in Africa
32 % desertification in Asia
19 % desertification in South America [48].

The Sahara alone expanded in the 50 years before 1977 by 650 000 km^2 [42].

Forests. The felling of trees in forests leads indirectly to the destruction of soil. Through the felling of trees the soil is often exposed to erosion by wind or water.

More than 5×10^6 ha of the tropical rain forest are wiped out each year to bring land into cultivation. Since 1970, farmers and ranchers in South America have converted more than 20×10^6 ha of wet tropical forests into cattle pasture [43].

The global current annual change of forest cover is depicted in Figure 11 [44]. According to this estimation, forest land is dramatically shrinking in South America (particularly Brazil), Central Africa, Southeast Asia and the Pacific Area, and in Russia. Rates of losses in the affected regions range from 100 000 to several million hectares per year. There is no indication that deforestation trends have been halted or reversed in those affected regions (see time series on Amazon deforestation in [45]).

Figure 11. Average annual change of forest per country (source: [44])

3.2.4. *Forecast*

The amount of soil available on the globe cannot be increased, whereas the human population is still increasing at a rate of 2 % or more annually in developing countries. Pressure on the resource soil is highly related to population growth. A map of the number of inhabitants per hectare agricultural land is shown in Figure 12 [30], [46]. It illustrates that pressure on the soil will be highest, where human population is already high and growing fast, while the area of cultivated land cannot be increased much further. A dramatic situation of almost continental extent exists in entire South East Asia. Some countries in Africa exhibit the same constellation of factors. In South America the situation is still less dramatic, because along with an intense population growth, the cultivation of land is increasing at the expense of a loss of forests.

Figure 12. Capita per hectare agricultural land (source: [30], [46])

Currently (2001) there are no indications of a major turn in the trend of increasing soil consumption and destruction. However, this trend cannot be continued arbitrarily long into the future, because the resource consumed is finite, and methods of enhancing yield from a given area of soil are limited. Critical ranges of soil consumption are attained in many parts of the world (Fig. 11, 11). The only way out of this dilemma seems to be the stabilization of human populations plus improved, sustainable methods of soil utilization.

[Top of Page]

4. Physical Damage to Soils

Karl Auerswald

Soils play a central role in ecosystems, e.g., for plant growth or the storage of rainwater, since soils exchange matter and energy with the atmosphere, the biosphere, and the hydrosphere. This exchange depends on their physical structure, e.g., on their depth and the structure of their pore system. Physical damage therefore impairs all functions of soils in the ecosystem.

4.1. Compaction [49-51]

Process. Natural compaction is caused by the soil's own weight, which leads to higher bulk densities at greater depths. Menisci of the water in the soil pores excert forces on the pore wall. These forces increase strongly with the drying-out of the soil and therefore stabilize aggregates. The force excerted by the water menisci is 1.5 kPa when the soil has been dried to the point where plants begin to wilt irreversibly. Further natural compaction is caused by the burden of the vegetation cover, especially under woodland; and by the intercalation of illuvial material (clay, iron oxides, carbonates) in the course of pedogenesis (luvizol, podzol, gleyzol). With increasing compaction of the soil, its shear strength, its bearing capacity and the capillary rise height increase. Soils loosened by cultivation are therefore reconsolidated, e.g., by rolling, after sowing.

The compactibility of soils decreases with increasing content of sand, stones, and organic matter; grain roughness; increasing aggregation (from blocky via prismatic and angular to subangular aggregates); rooting; and preconsolidation.

Damage. Only above a certain limit does compaction harm plant growth. In what follows, this compaction is called *excessive compaction*. When a compaction becomes excessive depends, apart from the soil properties, greatly on the weather and thus changes in the course of the year and from year to year [52]. In dry seasons a fairly high soil density is advantageous, because of the faster capillary water supply. In wet seasons, on the other hand, a low density is advantageous, because the soil then contains more coarse pores draining the excess water. Since the weather changes, it is also impossible to quote an optimum soil density. If the bulk density deviates from those shown in Figure 13, however, on average reduced yields have to be reckoned with under Central European climatic conditions.

Figure 13. (A) Optimum bulk density for soils of different texture; (B) change in yield of grain, potatoes, and sugar beet on deviation from the optimum bulk density (according to [71], modified)

Excessive compaction harms plants in all crop stages, but especially in the early stages. Compacted soils warm up more slowly (increased thermal conductivity, increased evaporation) to the temperatures necessary for germination and N mineralization, and the young plants develop only a weak root system. In the later stages, root development in compacted soils is more shallow and less dense. This lowers the nutrient uptake and impedes root respiration. The susceptibility to root diseases increases and in leguminous plants fewer root nodules are formed. Even with sufficient water and nutrient supply, plants react to compaction with a modified hormone balance, which reduces their growth [53].

The damage due to compaction is difficult to quantify, since large differences occur over the years and even within one field. Estimates with grain crops assume mean yield reductions of 5 –15 %. Other crops, especially root crops, react more strongly than grains. In addition to the losses of yield, the harvest is more difficult (clods during the potato harvest). The products have a lower quality (more clinging dirt in sugar beet, deformations in carrots). The tractive force requirement and machine wear during soil cultivation rise. (If compaction

causes only 5 % more slip, the tire wear already increases by 20 %.) The soil compaction can persist many years, especially if the subsoil has been compacted. Up to 50 years persistence has been reported [54].

Excessive compaction does not occur only in mechanized agriculture but in all soil uses, also during forestry [54] and as the result of cattle tracks on pastures [55]. In modern agriculture the loads and the number of machine passes have risen, increasing the compaction risk. The loads rose because the yields increased through the intensification of agriculture and an increased stocking of pastures with cattle became possible. In addition, to reduce the working costs the operating widths were increased and larger tractors, which can move the greater loads and are more convenient, were used. Particularly high loads on the soil occur in lime and slurry spreading and in the harvesting of crops of high water content (sugar beet, potatoes, green maize). The number of passes increased, because a well-devised system of agriculture necessitates, among other things, intensive tillage, fertilization in many small doses and the regular application of pesticides and growth regulators. In particular the fungicides are frequently sprayed after rainstorms because of the high risk of infection at that time. But at that time also the bearing capacity of the soil is low. In grain cultivation, 10 – 15 passes are customary today and in the case of more intensive crops (especially, e.g., hops) considerably more. Five passes, which are necessary for the sowing of barley, already cover 91 % of the field with tire tracks [50]. Compaction is a problem particularly in perennial crops, such as hops and wine, and in fruit plantations, since the same tire tracks are always used and very many passes are necessary.

Loosening. Freezing and thawing, swelling and shrinking, soil animals (the edaphon), and roots loosen the soil naturally. Roots displace the soil mainly to the side (radial pressure: 0.5 –1 MPa) and because of that compact it in addition, but create the vertical pores necessary for gas exchange and percolation. Earthworms also mainly displace and compact the soil. Because of their small axial force (0.1 MPa) they require zones of weakness (cracks), into which they penetrate in order to widen them. If the soil strength is higher than the radial forces that the earthworms can exert (0.2 MPa) [56], this strategy fails and the earthworms then loosen by ingesting compacted soil and transporting it to the soil's surface. Since this is exhausting, they loosen only slowly and only in cases when displacement is no longer possible but at the same time their other living conditions (e.g., availability of food) are advantageous.

Frequency and intensity of frost (up to 200 MPa at –20 °C) and swelling and shrinking (up to 2 MPa in Central Europe) decrease with increasing soil depth. In Central Europe the soil at a depth > 0.4 m freezes on average less than 10 times per year. Since freezing and thawing or shrinkage must occur many times before a compaction is loosened, the compaction in the subsoil persists for a long time. It is therefore especially problematic there.

In the surface soil, which is loosened considerably faster by natural processes, humans also intervene with tillage. In doing so they create above all coarse pores between the clods, but cannot loosen the clods themselves. Natural processes are necessary for that.

Protection Measures. Excessive compaction can be avoided by larger supporting contact areas of agricultural machines (dual wheels, cage wheels, wide-section and ultra-low pressure tires, more axles, tracked vehicles). The contact area can be raised further by reducing the tire inflation pressure, the use of radial instead of cross-ply tires and a small tire profile. Since as a result of larger contact surfaces the compacted fraction of the surface increases and pressure decays slower with depth , an improvement is achieved only if the contact pressure is decreased by more than 50 % [50]. The critical contact pressure is considered to be 60 – 80 kPa.

Above all, heavy loads should be avoided, since with heavy loads the compaction depends more on the load than on the contact pressure and penetrates deep into the soil. The critical wheel load is considered to be 30 kN [50]. Faster passing compacts less deeply (e.g., at 1 km/h, 28 cm deep; at 12 km/h, 16 cm deep). However, the compaction and structure deterioration at the soil surface rises as a result, since the shearing of the soil increases.

Because the optimum density to obtain high yields depends on the weather, a well settled soil with rapid capillary water supply is advantageous, if large vertical pores, e.g., earthworm channels, regulate excess water and gas exchange and a mulch cover simultaneously reduces evaporation losses. These conditions are ideally present in the case of the no-till cultivation system. In the no-till system tillage is replaced by chemical weeding with herbicides. The crop residues accumulate at the settled soil surface where they supply food for earthworms over a long period. Under this system the soils are also more stable to compaction because loads are well supported in the settled soil and the compaction of vertical coarse pores is more difficult than that of horizontal ones. Despite these advantages, the no-till system has hitherto been successful only in isolated cases because, among other reasons, the lack of working-in of crop residues causes problems with plant diseases which survive in the crop residues.

4.2. Erosion [57], [58]

Soil erosion is the loss of soil through the action of wind (wind erosion) or water (water erosion). The water can originate from rain, dew, or snowmelts. Transportable soil particles are initially detached from the assemblage and then transported away by water or wind. Additionally, special types of erosion are caused by tillage (tillage erosion) and creeping snow.

Wind Erosion. Small aggregates and in particular loose sand particles are caught and dragged along by the wind and roll or saltate along the soil surface. On impact these particles loosen further particles that initially are still bound and accelerate them. As a result these particles also can be caught and transported by the wind. The amount detached and transported increases in the wind direction. The detached fines (clay, organic material) are transported very far as aerosols, while the sand, in rolling and jumping motion, is usually soon redeposited. Consequently a loss of fines, which are important for the soil's productivity, occurs while sand accumulates.

Particularly susceptible to erosion are fine sandy soils, because they are only weakly aggregated, and peaty soils which, because of their low specific gravity, can easily be blown away when they dry out at the surface. The high wind speeds necessary occur particularly in spring and autumn storms. In these seasons the fields are often inadequately covered with vegetation. Large fields without fairly high structures (hedges, ridges) at the edges favor high wind speeds at the soil surface.

Water Erosion. Transportable particles are detached by striking raindrops, air entrapment by rapid wetting, dispersion, and shear forces of the runoff. (When water is imbibed from both sides of a capillary pore, it compresses the entrapped air. Air pressure may be strong enough to disrupt the aggregate.) The detached particles are transported by lateral splash and above all by the water running off. Sheet erosion occurs if the detachment by the runoff is small. With increasing detachment the runoff cuts its way in. If this takes place at many points simultaneously, *rill erosion* occurs (depth of the rills is usually <10 cm). If the runoff concentrates, the rills become fewer and deeper. It then comes to the point of *ephemeral gully erosion*. In this case the channels can still be regularly refilled by the tillage. Still deeper cutting-in (>30 cm) leads to *gully erosion*. *Tunnel erosion* occurs when a readily dispersible subsoil is washed out below a relatively stable topsoil, e.g., one interlaced with roots.

Water erosion is especially high for soils rich in silt and poor in organic matter, which have a low stability in water and easily form transportable particles. The erosivity of the rain increases approximately as the square of the rain intensity. For this reason summer thunderstorms with their high intensities (>10 mm/h) are particularly erosive. In early summer they impact — above all in the case of row crops such as maize, beet, potatoes, and soya — on a surface which still has only a sparse vegetation cover, and can cause large soil losses. With increasing slope and size of the surface drainage area (dependent on slope length and slope shape) and with decreasing roughness of the soil surface, the transport capacity of the runoff rises. In the absence of cover, snowmelts likewise can lead to erosion, since the frost destabilizes the soil.

Extent. Natural ("geological") erosion is at a maximum in semi-arid to arid regions because of the scattered vegetation cover there. Rare but in some cases violent rains or strong winds can therefore trigger off considerable erosion. High erosion losses are natural in the mountains also, owing to the steep slopes and frequently unfavorable vegetation conditions. But erosion is principally a problem of farming, because this at times leaves soils bare, and wind and water can then attack. Wind erosion occurs above all near coasts, where high wind speeds and sandy soils are common. Leaving aside a few areas, it is less important than water erosion. The amounts of soil lost through wind in the United States are assumed to be less than 1/10 of those lost through water [59]. During farm use in moderate latitudes, soil erosion by water is frequently of the order of 10 t ha^{-1} a^{-1}, but soil losses of up to 200 t ha^{-1} a^{-1} have also been observed over fairly long periods [60]. Probably the highest soil losses, of the order 1000 t ha^{-1} a^{-1} [61], occur in South-East Asia (see Section Soil Destruction) [62]. High soil losses are reported for other tropical regions also (Brazil, West and East Africa, and India) [58].

Damage. In wind erosion, saltating grains of sand, above all, damage the plants by exposing, covering, or by injuring the cuticle. In water erosion, rainfall flows unproductively away and cultivation is made difficult by uneven crop development, and by gullies and channels. In both forms of erosion, nutrients and pesticides are lacking at the eroded sites and overdosed at the deposition sites.

Aside from these short-term forms of damage, cumulative, irreversible, long-term damage occurs because the soil depth and the water- and nutrient-holding capacity decrease. This damage is particularly marked where unfavorable parent material, such as gravel, hard rock, or acid subsoil, is covered with a fertile but shallow material such as loess.

To the on-site damage to the eroded areas must be added the off-site damage at the points where the sediment and runoff accumulate. Examples are the soiling of roads and houses, the siltation of waters, and the input of nutrients, pesticides, and heavy metals into waters and other neighboring ecosystems.

In some cases erosion can also be advantageous. Thus the soil fertility rises if an impoverished or acidified topsoil is eroded and exposes more favorable material. In addition the input of soil into waters can reduce the concentration of dissolved nutrients by sorption if high nutrient concentrations are caused by point sources.

Erosion Protection [63]. A permanently covered soil surface offers the best protection against erosion. 30 – 50 % covering is usually sufficient, since a vegetation cover reduces erosion more than proportionate. The covering protects from drop impact, reduces wind speed and runoff velocity, raises the soil moisture at the surface, and promotes vertical pore formation by earthworms. The cover need not be present permanently, but only during the seasons of erosive rain or winds. In conventional farming the soil is least covered directly after sowing. In minimum or conservation tillage a sufficient cover can also be guaranteed after sowing.

Besides that, runoff and wind can be slowed down by a rough surface, which is obtained by cultivating transversely to the slope or to the main wind direction. A small-scale, varied land-use system in which areas with different degrees of erosion protection adjoin each other prevents that too much runoff or eroding saltation material is collected and that high wind velocities arise. This mutual protection of different crops is deliberately made use of in strip cropping, in which the individual crops are grown in strips of any length and a width of usually 10 – 50 m, running transversely to the slope or to the main wind direction. The runoff can be slowed down further by terraces, and the wind by wind breaks.

Models. Because of the great variability of erosion in time and space, many prediction models have been developed to estimate its extent and to plan protection measures. Far more and better supported models exist for water erosion than for wind erosion (Table 8). The oldest, best known, and most used model of water erosion is the Universal Soil Loss Equation (USLE) [64], on which many more recent models are based. Its latest version is the Revised Universal Soil Loss Equation (RUSLE) [72]. These models differ in the processes considered (wind, water erosion; sheet, gully erosion), in the time scale (single-event, long-term models), in the spatial scale (field, drainage area), and in the modeling technology (stochastic vs. deterministic; process oriented vs. lumped). Table 8 assembles the most common models with their main applications. Many have been extended beyond this.

Table 8. Main areas of application for five common erosion models (special adaptations were not considered) [a]

Tillage Erosion [65]. Tillage lifts up the soil normally to the soil surface. The soil then falls back vertically due to gravitation. On sloping land, the upward movement thus follows a different path than the downward movement (Fig. 14). This causes a net movement downslope. This movement occurs in any case where the soil is lifted by tillage, i.e., also in cases where the tillage direction is perpendicular to the slope or where tillage operations are carried out with changing directions. Additional movement results where tillage direction is downslope only. This is the case when traction forces do not allow upslope tillage on very steep slopes or in poorly developed agricultures where tillage is carried out with the help of animals or with hand hoes.

Figure 14. Movement of a representative soil block during tillage

The amount of soil translocation increases with tilling depth, slope angle, lifting height and numbers of tillage operations. Tillage translocation can thus be reduced by reducing tillage frequency and depth. On a straight slope, the downslope loss at a certain point is fully compensated by the gain from upslope. A net loss hence only results at the upper field edge where no input from upslope occurs. Correspondingly, a net gain occurs at the lower field edge which receives input from upslope without downslope losses. This characteristic distribution of loss and gain areas leads to the development of terraces after long-lasting land use in landscapes with small field layout like in Middle Europe. Loss and gain are also not balanced on slopes where slope steepness changes. When slope steepness increases, downslope soil transport is larger than the input from upslope resulting in a net loss. This causes the characteristic strong soil truncation of slope shoulders and crests which cannot be explained by water erosion because erosion should be larger downslope where increasing slope gradient and amount of runoff both cause an increase in transport capacity. Where slope gradient decreases downslope like at toeslope positions, soil input from the steeper upslope area is larger than the soil movement downslope. This surplus soil material then accumulates. In contrast to water and wind erosion, in total no soil is lost from a field and no selective loss of the fines occurs. Damages are only caused by the uneven soil distribution with tillage erosion. In slope positions prone to tillage erosion (upper field edge, crests, shoulders) soil losses can be much larger than the losses by water and wind erosion.

4.3. Building Over and Sealing [66-68]

Building over and artificial sealing extensively damage all soil functions; infiltration and gas exchange, for example, are impeded, temperature buffering is impaired, and plant growth is scarcely possible any more. Even a minor amount of sealing may have consequences. Thus a land reconsolidation with asphalting of only 6 % of the surface by field roads increased peak runoff twelvefold [69]. Despite the higher runoff, the net percolation is in some cases greater under sealed areas (e.g., asphaltic surfacings) because of the greatly reduced evaporation. This impairs the microclimate in sealed areas (higher temperatures and lower atmospheric humidities by day, lower temperatures by night). Moreover, additional damage to the neighboring soils often emanates from sealed surfaces such as roads, owing to the drift of combustion residues or thawing salt, for example. The soils in the vicinity of sealed areas are often greatly changed by deep mixing, input of artificial products such as bricks, asphalt or concrete, or by covering with natural or anthropogenic substrates. Therefore, a significantly larger proportion of soils is damaged by urban activities than the sealed area itself.

In contrast to compaction and erosion, sealing affects limited areas only, but there frequently leads to a complete loss of soil. In some industrialized countries more soil is being lost annually by urban development than by erosion on arable areas, although the area affected by development is only 0.2 % of that affected by erosion.

Whereas compaction and erosion have natural causes also and are merely increased by humans, they alone are responsible for building over. Nevertheless, just this kind of damage is increasing more and more, especially in industrialized countries. There, the settlement area rises by ca. 1 % per year, since the area needs of the individual increase and there is a trend to styles of residential construction that use up much soil area. In order to limit the damage or partly to cancel it, the following measures are necessary in case of existing or planned building over:

1. More compact styles of construction with smaller consumption of soil area per unit of useful area
2. Land recycling, i.e., redevelopment of formerly developed areas instead of allocation of new construction sites
3. Replacement of coverings that greatly impede mass transfer by more permeable coverings (Fig. 15)
4. Removal of sealing where it is unnecessary (e.g., central strip between the track grooves of roadways)

Figure 15. Relative infiltration of precipitation with different kinds of sealing (according to [66], modified)

As a rule these measures are also perceived as an esthetic gain (e.g., [70]).

5. Effects of Anthropogenic Substances on Soil

Norbert Litz, Robert Mayer, Alexander Stoy, Kassem Alef, Helmut Kerndorff

5.1. Persistent Pollutants [78-81]

The growing production and use of organic chemicals, their worldwide dissemination, and ignorance about the behavior of substances in the environment are some of the reasons why persistent organic substances can be detected in the environment, and not only in industrial conurbations. About 10×10^6 chemical substances are registered with the CAS. Day after day about 1500 new substances are registered, that is, 500 000 new substances are developed or registered every year. But of these 10×10^6 substances only about 100 000 are produced and traded industrially at present, and of those, according to information from the German Association of the Chemical Industry (Verband der Chemischen Industrie, VCI) about 5000 substances are produced in amounts of more than 10 t and 1080 in amounts of more than 1000 t/a [82]. By comparison with the number of substances produced and traded, the number of persistent substances known up to now is small.

5.1.1. *Definition and Criteria*

Persistent compounds are durable substances that are stable in the biosphere under natural climatic and soil conditions and also towards soil flora and fauna (the edaphon). Substances can be called persistent whose total degradation in the biosphere does not occur in one vegetation period. To be classified as nonpersistent half of the amount of a substance must be degraded within 1.5 months. Such criteria are also drawn up for plant-protection agents [83]. OTTOW defines persistence as the time required for 95 % degradation [84]. Persistent compounds are frequently xenobiotic and are among the environmental chemicals.

5.1.2. *Sources and Entry Paths*

Chloroorganic compounds in particular represent the bulk of persistent compounds in the environment. At present, about 3×10^6 t of chloroorganic compounds are produced annually in Germany. Mainly low-boiling chlorinated hydrocarbons are emitted into the environment in noteworthy amounts, i.e., between 60 and 90 %. Pollutants are released not only from production sites but also during the consumption and application of products [85].

Pollutants can enter the soil via the *air path* (dry deposition); the *water path* (sewage water, precipitation, surface water, irrigation water, i.e., wet deposition); and via *organic solids*, such as sewage sludges, composts, organic residual substances, or agricultural inputs (soil-improvement agents, fertilizers, manure, plant-protection agents).

Air Path. The importance of the air path for the entry of organic compounds into soils is recognized more and more. For 1986 the total emission of volatile organic substances into the atmosphere originating from the Federal Republic of Germany was estimated at 2.45×10^6 t. According to a description of SCHLEYER et al. for the Federal Republic of Germany before 1990 (area 248 798 km^2), 7000 t/a benzene, 250 000 t/a toluene, and 250 000 t/a nonvolatile chlorinated hydrocarbons were released and gave calculated mean concentrations in the rainwater of 336 µg/L, 1200 µg/L, and 1200 µg/L, respectively [86].

Organic substances can enter the soil in gas form, dissolved, or particle-bound. The relative importance of individual kinds of deposition is determined by the substance properties, the particle supply, the kind of emission, and meteorological parameters. Substances with low vapor pressure, e.g., polychlorinated aromatic biphenyls (PCBs) are present in the air mainly in the gas phase and hardly at all in the dissolved aqueous phase [87]. Similar results have been obtained for polycyclic aromatic hydrocarbons (PAHs) and other chloroorganic compounds [88]. Dry deposition means the deposition from the atmosphere onto the earth's surface. Substances can be deposited from the gaseous or particle-bound phase.

Wet Deposition. Studies on wet deposition (i.e., entries as a result of rain, snow, mist and dew) have been performed in the case of low-boiling chlorinated hydrocarbons and aromatics [89-92]. The behavior of PAHs and PCBs in rainwater has also been studied [91], [93-95]. A survey can be found in [96]. CAPEL et al. [97] determined depositions of *n*-alkanes in Switzerland at concentrations of 150 – 170 µg m^{-2} a^{-1} by mist and at 400 – 4000 µg m^{-2} a^{-1} by rain and depositions of PAHs at 90 – 900 µg m^{-2} a^{-1} by mist and at 100 – 600 µg m^{-2} a^{-1} by rain. In the United States, PAH depositions of 350 µg m^{-2} a^{-1} for urban locations and 100 µg m^{-2} a^{-1} for rural areas have been determined.

Surface Waters. The pollution of soils by organic pollutants through infiltration of contaminated surface water (caused mainly by sewage waters) tends to decrease. However, the pollutants concentrations in surface waters are distinctly higher than the concentrations in rainwater, sometimes by a factor 10 or more [98]. When flooded and irrigated by surface water, soils come into contact with its constituents. Areas of flooding therefore often constitute endangered areas [99].

Sewage Water and Sewage Sludge. Some substances, e.g., surfactants, enter the soil environment exclusively via sewage water and sewage sludge. It is estimated, for example, that large amounts of linear alkyl benzene sulfonates remain in the sewage sludge [101], [102]. Leakages in sewage water systems can also contribute significantly to soil pollution.

Within the framework of measures for groundwater enrichment, old shutdown irrigation fields are increasingly being reactivated and rainwater percolating areas (infiltration ponds) used. Studies on substance retaining powers of the upper active soil layers and on the contamination of the underground and groundwater showed that an accumulation of PAHs, PCBs, and dibenzodioxins/dibenzofurans in particular occurs in the mud zone of infiltration ponds [103]. In the sediment of such a pond, 15 µg/kg toluene, <10 µg/kg benzene, and <1 µg/kg trichloroethylene and tetrachloroethylene were determined. The PCB contents were up to 260 µg/kg and the PAH contents between 1 and 2 mg/kg d.m. (dry matter). Hexachloro- and pentachlorobenzene also were detected in traces.

The revision of the German TA Siedlungsabfall (Technical Instructions for Estate Waste) will lead to an increasing consideration of *organic solids*, such as sewage sludge, composts, organic residues, etc. In Germany, ca. 30 % of all municipal sewage sludges are spread in agriculture. The concentration of some pollutants in sewage sludges is therefore subject to limit values: thus, e.g., the dibenzodioxins and dibenzofurans to 100 ng TEQ (Toxicity Equivalents of the BGA)/kg d.m.; the PCB congeners 28, 52, 101, 138, 153, and 180 each to 0.2 mg/kg d.m.; and AOX (adsorbable organic chloro compounds) to 500 mg/kg d.m. The pollutant load of sewage sludges — on which limit values are imposed in the German regulation on sewage sludge (Klärschlammverordnung) [104] — has continuously decreased since the 1970s. The extreme and mean values of different pollutants in more than eighty-nine different German municipal sewage sludges in 1989 are listed in Table 9 [105].

Table 9. Extreme and mean values of various organic pollutants in sewage sludges (data in mg/kg d.m.) [105]

Compound	Minimum	Maximum	Mean value
Fluoranthene	0.26	9.38	1.495
Benzo[*b*]fluoranthene	0.13	4.07	0.665
Benzo[*k*]fluoranthene	0.05	1.97	0.36
Benzo[*a*]pyrene	0.07	5.16	0.57
Indano[1,2,3-*cd*]-pyrene	0.03	3.07	0.36
Benzo[*g,h*]perylene	0.03	2.50	0.36
Di(2-ethylhexyl)phthalate	15	314	110.9
AOX	42	4400	360.9
PAHs (total)	1	21.81	5.508

In the case of PAHs the proportions by mass were between 1 and 21.81 mg/kg d.m. for individual PAHs, with the exception of fluoranthene (0.26 – 9.38 mg/kg d.m.). Benzo[*a*]pyrene reached values between 0.07 and 5.16 mg/kg d.m. [105]. Contamination of the sewage sludges by surfactants (linear alkyl benzene sulfonates and nonylphenol ethoxylate) in somecases reaches the g/kg range and can strongly influence the behavior of other pollutants. The mineral oil hydrocarbons also reach similar orders of magnitude (g/kg d.m.).

5.1.3. *Processes in Terrestrial Soils*

Distribution. The processes in terrestrial ecosystems determine the distribution of chemicals in the soil. The distribution via the *air path* is influenced by climatic/meteorological factors (main wind direction, air temperature, frequency and intensity of precipitation, terrain topography, distance from emitter). The spread via the *water path* by seepage and infiltration is influenced by the intensity and frequency of the water input, the permeability of the soil, the properties of chemicals and the chemical properties of the soil. If an ecosystem is regarded as a compartment, the input and output of substances must be considered. Both processes are time-dependent. Between the two processes fixation, reaction, or mineralization occurs.

Sorption. Organic pollutants are subject in the soil to the same processes as, e.g., pesticides. After the pollutant enters the soil, it may be sorbed on solids (soil matrix) or remain in the gas phase or solution phase. Substances that have a higher density than air move downwards in the soil, while substances that are lighter than air can also be transported upwards.

The *bioavailability* is closely connected to the effect thresholds. The toxic threshold value is below the no observed effect level (NOEL, ⟶ Toxicology – Toxicological Studies: General Aspects). For estimating inputs over area and time and their effect on the ecosystem, the concept of critical load and critical level [106] is used. This means the pollutant loads that, for certain organisms in the soil and plants, still cause no effects.

Organic pollutants are bound in the soil as a function of their water solubility, molecular structure, and functional groups. The soil is basically a multiphase system, with solid, liquid, and gas phase. The liquid phase can be broken down spatially into a hydrophobic and a hydrophilic phase and therefore considerably changed in its properties by dissolved organic substances, organic complexes, and suspended particles [107]. Contaminated soil water can contain miscible or immiscible organic phases of cosolvents that can considerably influence the sorption behavior of contaminants [108-111]. The soil sorption coefficients of chemicals decrease semilogarithmically with increasing concentration of the cosolvent in water. In addition to the type of bonding (van der Waals, hydrophobic, hydrogen-, charge-transfer, complex, and ionic bonding, induced ion – dipole or dipole – dipole interactions, see also [112]), the soil properties (contents of humus, clay, oxides, and hydroxides, the pH value, redox potential, and charge [113]), and the properties of the chemicals (water solubility, molecular size and structure, lipophilicity, acidity, polarity, vapor pressure, [114]) are also important. The sorbents contained in the soil have very different properties. The organic matter is an important sorbent for all kinds of organic compounds, e.g., cationic or anionic, polar or nonpolar, because it can interact with the functional groups contained in these substances. The degree of decomposition of the organic matter has to be taken into account. Thus, the sorption capacity increases in the sequence mor, moder, and mull. Oxides and hydroxides can be further important sorbents, especially for anionic organic compounds. Clay minerals, because of their negative surface charge, are capable of binding cationic compounds as well as negatively charged compounds, such as basic nitrophenols and anilines after protonation [115]. The bonding relationships are mainly determined in batch experiments. However, more realistic predictions on sorption are obtained in leaching tests. Sorption constants are usually smaller in leaching tests since the penetration into the soil particle is less. The sorption is also time dependent, organic compounds are initially bound at the bonding sites at the surface of clay minerals and humus. Transposition and incorporation into the sorbents can occur gradually. Only in this way can it be explained that bound residues can scarcely be desorbed from the soil matrix with aqueous solution [116], [117].

Elimination here means the sum of the chemical, physical, and biological degradation processes in the soil, including volatilization and loss because of uptake of the substances by plants and seepage into the groundwater (nonextractable substance residues are often considered being part of the eliminated portion). The first degradation step is often a *hydrolysis*, which can proceed only in the presence of water. The rate of hydrolysis is influenced by the pH value and by the presence of metal cations. Hydrolysis is especially important in inputs via the air (precipitation) and surface waters. In the soil, *reductive and oxidative processes* can lead to chemical alteration of substances. Oxidative reactions occur with “reactive oxygen species” or molecular oxygen (autoxidations) in soil and bodies of water. Abiotic reductions possibly occur in the degradation of pentachloronitrobenzene under anaerobic conditions to pentachloroaniline [118].

The *physical degradation* is based on photochemical and photophysical processes, which are mainly restricted to the soil surface. Dechlorination reactions of chlorohydrocarbons are typical photoreactions. The photomineralization of adsorbed organic pollutants is based on the absorption of UV light of fairly long wavelengths (>290 nm), as is assumed for pentachlorophenol (PCP) [119]. Dibenzodioxins and -furans were 90 % dechlorinated within a week in soils [120].

Organic compounds are mainly degraded biologically (metabolic or cometabolic). Chemical and physical degradation plays a part with substances that are degradable with difficulty, for example, highly chlorinated dibenzodioxin congeners (octa- and heptachlorodibenzodioxins).

The persistence of a substance depends on its physicochemical properties and the soil properties, including the soil's microbiological potential. According to OTTOW [84], the degradation of near-natural compounds is mainly metabolic and that of xenobiotics mainly cometabolic. Persistent substances usually have unphysiological, chemically stable groups. These include, e.g., C–Cl, C–SO_3H, C–NO_2 groups, trisubstituted N atoms, quaternary carbon atoms, ether bridges, polychlorinated compounds, chlorine substituents in benzene rings in the *ortho* or *meta* positions, pyridines, and long-chain hydrocarbons. Furthermore, these substances are persistent because of their low water solubility and bioavailability and large molecular size. They are mainly cometabolic and frequently only to very stable metabolites (“dead-end” metabolites).

In soils that contain various persistent organic pollutants, the degradation may be reduced. In saturated, anaerobic soils, other microorganisms are usually necessary for the degradation of a substance than under aerobic conditions. Many chlororganic substances, for instance, are degraded more easily by reductive dechlorination under anaerobic than under aerobic conditions [121]. Alternately moist and dry conditions therefore increase the degradation efficiency of soils. The oxygen supply of the soil influences the activity of aerobic microorganisms that not only use oxygen as an energy donor but bring about hydroxylations of aliphatics and aromatic compounds by means of microbial oxygenases [122-124]. The degradation rate usually decreases with increasing soil depth, but a heterogeneous distribution of the organism density can lead to quite different degradation rates [125], as has been shown in the cases of methanol, phenol, and *tert*-butanol. The degradation is in general distinctly slower in winter because of lower temperatures [100].

Volatility. The transfer of substances from the soil into the atmosphere is known as volatilization or volatility. For aqueous solutions Henry's law constant describes the ratio of the concentration of a substance in the gas phase to its concentration in the solution phase. The volatility of highly volatile adsorbed substances is liquid-phase controlled and that of low-volatility substances is gas-phase controlled. In addition, the volatility is strongly influenced by the water solubility of the substance, the vapor pressure, the temperature, the soil moisture, and the humus content of the soil. Substances can as a rule be more easily released from moist soils, because they are more easily desorbed from the aqueous phase. The soil water can moreover make an important contribution to the evaporation of substances at the soil surface that are delivered subsequently from deeper soil layers. Diffusion plays a certain part in the subsequent release at the soil surface and therefore in the volatility of chemicals. Even low-volatility compounds, such as dibenzodioxins/dibenzofurans, with extremely persistent properties can be volatilized into the atmosphere [126].

Uptake by Plants. The uptake of organic pollutants in plants is determined by their water solubility, molecular mass, and lipophilicity, as well as their concentration in the soil and the soil properties. The uptake can occur via the root with the transpiration stream; as a result of uptake via the leaves (dry and wet deposition); and by dust particles, degassing and spraying of the soil by the impact of rain.

5.1.4. *Persistent Organic Compounds*

The persistent organic substances also include organochlorine compounds, such as hexachlorocyclohexane (HCH) hexachlorobenzene (HCB), DDT, and 1,1-dichloroethenylidenebis-(4-chlorobenzene) (DDE), that have been used as pesticides (⟶ Insect Control – Organochlorine Insecticides). These substances and those dealt with below have in some cases been detected worldwide in various environmental media (water, sediment, soil, organisms, and the atmosphere). Their contents in environmental media decrease only slightly, even over fairly long periods.

5.1.4.1. *Chlorinated Aliphatic Hydrocarbons*

Some haloalkanes (used as organic solvents) behave as persistent compounds. The low-boiling chlorinated hydrocarbons occur ubiquitously, they are partly of biological origin. Algae in particular are capable of forming halogen compounds. It is assumed that ca. 10 000 t/a of organohalogen compounds are emitted into the atmosphere worldwide from macroalgae [127]. In 1987 about 250 000 t/a of low-boiling chlorinated hydrocarbons of industrial origin were consumed in the Federal Republic of Germany and at the same time partly emitted into the environment [128]. Relative to the average rainfall of 837 mm/a, this would yield a hypothetical mean concentration of 1.2 g per milliliter rain water, i.e., at uniform deposition ca. 1 g per square meter soil surface [86].

The most important low-boiling chlorinated hydrocarbons are dichloromethane, 1,1,1-trichloroethane, trichloroethylene, and tetrachloroethylene. Some of the low-boiling chlorinated hydrocarbons, e.g., tetrachloroethylene, have a carcinogenic potential. They reach the environment via the air and via the sewage water path, from contaminated sites, and by accidents. Some of the low-boiling chlorinated hydrocarbons are quite stable in the atmosphere (e.g., 1,1,1-trichloroethane has a tropospheric half-life of 63 a [129]) and are photooxidized (e.g., tetrachloroethylene to trichloroacetyl chloride). After hydrolysis, the water-soluble, low-volatility trichloroacetic acid [130] is formed in amounts of ca. 6 g d^{-1} km^{-2}, which yields an estimated deposition of 4 g ha^{-1} a^{-1}. SCHLEYER et al. [86] estimate depositions of 23 g ha^{-1} a^{-1} (in a spruce stand) and 6 g ha^{-1} a^{-1} (in open land) (Table 10) [86]. Trichloroacetic acid is also formed in the photochemical degradation of trichloroethylene. Carbon tetrachloride is especially stable in the atmosphere (half-life 60 a). Many low-boiling chlorinated hydrocarbons accumulate in soils relative to the atmosphere (see Table 11, e.g., $CHCl_3$, CH_3CCl_3, C_2Cl_4), but their outgassing as well as their metabolites also have to be reckoned with [131].

Table 10. Mean concentrations of selected organic parameters in rainwater calculated from four measuring stations and deposition rates determined from them; basis of calculation is a mean rainfall quantity in Germany of 837 mm/a [86]

Substance	Spruce stand		Open land	
	Mean concentration, ng/L	Deposition rate, g ha^{-1} a^{-1}	Mean concentration, ng/L	Deposition rate, g ha^{-1} a^{-1}
AOX	29 000	243	4700	39
Chloroform	56	0.5	14	0.1
Trichloro- acetic acid	2800	23	730	6.1
Toluene	47	0.4	48	0.4
ϒ-HCH (lindane)	36	0.3	39	0.3
Dibutyl phthalate	310	2.6	265	2.2
Di(2-ethyl- hexyl) phthalate	790	6.6	580	4.9

Table 11. Contents of various low-boiling chlorinated hydrocarbons (LBCHs) in soil atmosphere and in the atmosphere of a forest in the Black Forest in 1989 (means of six measurements) [92]

LBCH	Soil atmosphere, µg/m^3	Atmosphere, µg/m^3
$CHCl_3$	41.8	0.167
CH_3CCl_3	2.27	1.3
CCl_4	0.5	0.66
$CHClCCl_2$	0.23	0.58
C_2Cl_4	2.98	1.85

The persistent low-boiling chlorinated hydrocarbons, the half-lifes of which in soils are more than 5 months, include in particular trichloroethylene, dichloromethane, trichloromethane, carbon tetrachloride, and vinyl chloride. Under *water-saturated conditions* the dominant degradation processes are reductive dehalogenation (e.g., with tetrachloroethylene), dehydrohalogenation (e.g., hexachloroethane to 1,1,1-tetrachloroethane), and hydrolytic dehydrohalogenation (thiolysis of the C–Cl bond in dichloromethane). In *anaerobic media* mainly higher halogenated alkanes are dehalogenated. Reductive dehalogenation depends on the redox potential of the reactants and requires an anaerobic medium [132]. *cis*-1,2-Dichloroethylene and vinyl chloride frequently accumulate as degradation products in groundwater, because of the slow transformation of vinyl chloride to ethylene. 1,1,1-Trichloroethane proves to be extremely persistent in water-saturated soils (half-life in the groundwater 2.8 – 19 a [133]). The assumption of slow degradation in water-saturated soil is moreover supported for tri- and dichloromethane [134], [135].

Under *aerobic conditions* haloalkanes are oxidatively dehalogenated by monooxygenases. In the case of C_1 haloalkanes, the corresponding aldehydes and carboxylic acids are formed successively. Mono- and dihaloalkanes in particular are degraded more rapidly under aerobic than under anaerobic conditions. The degradation of carbon tetrachloride is quite slow, even under aerobic conditions. During degradation by the various oxygenases the metabolite trichloroethylene epoxide, as a cell poison, inhibits the further elimination of trichloroethylene and trichloromethane [136].

The degradation should not lead to toxic “dead-end” metabolites such as *cis*-1,2-dichloroethylene or vinyl chloride. In the degradation of dichloromethane, which is regarded as easily degradable, the presence of 1,2-dichloroethane causes a competitive inhibition of the dichloromethane-degrading enzymes [137]. Dichloromethane is degraded more strongly (faster) in presence of acetate than in its absence [138]. The presence of formate also had a stimulating effect [139]. Formate can thus be advantageously used in in situ remediations. Low-boiling chlorinated hydrocarbons are weakly bound in the soil, because of their high water solubility (up to 20 g/L) and high vapor pressure. The main sorbent is the organic matter of the soil. The Freundlich sorption constants K (K_{OC} relative to the humus content) vary from <1 to 300. The low binding by the soil also explains the large number of nearly 3000 cases of groundwater pollution by chlorinated hydrocarbons reported to the German water authorities in 1990 [140]. Remediation measures that enhance the bioavailability of chlorinated hydrocarbons by increasing the desorption from the soil matrix, e.g., by surface active substances, should only be used if no additional risk arises to soil and groundwater.

5.1.4.2. *Aromatics and Chlorinated Aromatics*

Aromatic hydrocarbons are among the most widespread organic compounds [141]. Thus, e.g., in the Federal Republic of Germany in 1985 alone, ca. 76.6×10^6 t of crude oil were distilled and subsequently processed to energy carriers and fuels. The motor vehicle fuels produced contained ca. 680 000 t of benzene, 2.4×10^6 t of toluene, and ca. 3.1×10^6 t of xylenes. Simultaneously, 1.6×10^6 t of pure benzene, 360 000 t of toluene, and ca. 470 000 t of xylenes were produced for further chemical processing [142]. According to an estimate of the Umweltbundesamt (UBA, Federal Environmental Agency) for 1982, the total emisson of benzene from motor vehicles, heating plants, and industrial production was ca. 60×10^6 t/a, but distinctly smaller amounts can be assumed today. At the end of the 1980s, the 70 000 t/a of benzene and 250 000 t/a of toluene were emitted into the environment by motor vehicle traffic. Despite the enormous amounts introduced into the environment, the benzene, toluene, xylene (BTX) aromatics can only be detected in small concentrations (0.1 – 1 µg/L) in water bodies. The concentrations in municipal sewage water are greater by a factor ten and industrial wastewaters can be loaded with 1 – 10 g/L. More than 90 % of the BTX is eliminated in sewage treatment plants. Annually, 3.5 t benzene are said to be introduced to the environment via sewage sludges and ca. 80 t into bodies of water [143]. The benzene contents of the air in urban zones are between 5000 –50 000 ng/m^3, in rural zones 500 – 5000 ng/m^3, and in remote areas <2000 ng/m^3. In the case of toluene, the pollution is 5000 – 10 000 ng/m^3 for urban zones, 1000 – 7000 ng/m^3 for rural areas, and ca. 750 ng/m^3 for remote areas. The concentration of the various xylene isomers varies from 800 – 70 000 ng/m^3 and from 200 – 1200 ng/m^3, no data being available for areas remote from sources [86], [144]. The ethylbenzene contents are also relatively high. In precipitation waters the pollution due to aromatics is higher by a factor of ca. 1000, depending on the distance from emitters. Thus, e.g., <220 ng/L toluene, <260 ng/L xylene (*m*-, *p*-), and up to 72 ng/L ethylbenzene are found in rainwaters [145]. Rain loadings of a similar order were determined in the Rhine – Main area and in the hills of Hesse, the concentrations being distinctly higher under spruce stands than in open land. This is a result of the effect of trees in “mopping up” air pollution. In both cases the loads were higher in winter than in summer.

No representative data are available for background concentrations in soils for BTX, but data exist for higher-chlorinated benzenes and phenols [99]: an average of 0.1 µg/kg d.m. was measured for pentachlorobenzene and 1 – 2 µg/kg d.m. for hexachlorobenzene.

In Switzerland the background values vary between 0.15 and 0.5 µg/kg d.m. for hexachlorobenzene [146]. According to studies of [147] and [148], the pentachloro- and hexachlorobenzene contents in the humus cover of forest sites (6.5 – 11.5 µg/kg d.m.) are distinctly higher than those of the mineral horizons (1 – 2 µg/kg d.m.) or of sites on open land (<5 µg/kg [149]). In forest soils near Linz [150], the hexachloro- and pentachlorobenzene contents were 0.38 – 0.4 µg/kg d.m. and in the humus cover 0.147 µg/kg d.m.

In the soils themselves, benzene, toluene, and xylene are only moderately bound. K_{OC} values are <100 for benzene, <500 for toluene, and <1400 for xylene (Table 12). The aromatics are bound mainly to the organic matter. The aerobic degradation of BTX in the soil is very rapid (half-lifes 2 – 16 d [151]). In water-saturated soils, on the other hand, these substances prove to be more stable; apparently volatilization often makes the main contribution to elimination [152]. The biradical oxygen molecule oxidizes BTX aromatics to phenols. Subsequently the ring opens. This process is inhibited under anaerobic conditions and only occurs at a sufficient rate if the ring is substituted by carboxyl groups. Thus, a strong benzene contamination in anaerobic underground was not degraded even after 4 years [153]. Strong persistence and small degradation under anaerobic aquifer conditions was also established for aromatics [154], [131]. This behavior is strictly related to the lack of molecular oxygen. After dissolved oxygen was supplied, a rapid degradation occurred [155]. On the other hand, a degradation could occur when ferulic acid (4-hydroxy-3-methoxycinnamic acid) [156] was present or iron reduction was possible.

Table 12. Sorption of aromatics and haloaromatics to organic matter [110], [130]

Substance	K_{OC}	Substance	K_{OC}
Benzene	60 – 100	Phenol	<100
Chlorobenzene	210 – 390	Chlorophenol	100 – 300
Dichlorobenzene	230 – 970	Dichlorophenol	300 – 700
Trichlorobenzene	4300	Trichlorophenol	100 – 570
Tetrachlorobenzene	85 000	Tetrachlorophenol	150 – 750
Pentachlorobenzene	11 400	Pentachlorophenol	300 – 950
Hexachlorobenzene	3900 – 11 800	Toluene	300 – 510
Ethylbenzene	300 – 600	*p*-Xylene	400 – 1400

Before aromatics are illuviated into the soil, they can evaporate into the air. Owing to the high vapor pressure of BTX, high volatilization rates are to be expected. In the atmosphere, benzene, for example, undergoes a photochemical degradation by OH radicals, NO_x, and ozone (⟶ Air – Photochemical Degradation).

The volatility of aromatics is used especially in the remediation of contaminated areas. Volatility depends greatly on the porosity and the moisture of the soil. The relative humidity (rH) at a certain water content of the soil determines the composition of the vapor phase of BTX, etc. very strongly. A stepwise increase of the relative humidity from 0 – 20 % produced a reduction of the binding of *p*-xylene to kaolinite [114]. At 67 rH only 50 % of the xylene remained bound. Compounds such as BTX with Henry's law constants of >10^{-3} bar mol^{-1} m^{-3} can be removed from the soil and groundwater by stripping [157], they can also be reduced relatively rapidly in bioreactors with 100 % turnover. Under field conditions the remediation measure was distinctly slower.

Chlorinated Aromatics. Chloro-substituted aromatics behave distinctly differently in the environment, especially in terrestrial ecosystems, from the pure aromatics. The sorption in the soil increases with increasing degree of chlorination. The solubility of the BTX and chlorinated aromatics in the soil can be raised by addition of vegetable oils or by biosurfactants formed by microorganisms, so that a more efficient remediation is possible via the water phase [158]. But the degradation can also be reduced if the toxic threshold concentration for microorganisms is exceeded. It has been reported that biopolymer-bound trichlorophenol was stable to degradation, and a negative effect of the surfactant on the microorganisms also being possible [159].

5.1.4.3. *Nitroaromatics and Aromatic Amines*

Nitroaromatics play a notable role in regard to the amount of inputs from the atmosphere. They are formed from BTX after photochemical reaction with NO_2 and OH radicals in the troposphere. Through rainfall nitroaromatics enter soil, leachates, and spring waters in low concentrations over a wide area [86]. As intermediate and end products in the production of plant-protection agents, pharmaceuticals, plastics, dyes, and explosives, they reach the environment in the course of their processing and use. Most important are the various nitrophenols, nitrotoluenes, nitroanilines, and pyridines, as well as chlorine-derivatives of these compounds. It is estimated for Germany that ca. 20 000 t of nitrophenols are emitted annually into the atmosphere or formed there [160]. Aromatic amines such as chloroanilines are determined in surface water in concentrations of 1 – 5 µg/L but also distinctly higher

values are found [161].

Because of their considerable toxicity to microorganisms and humans and their mutagenic potential, which is in some cases considerable, nitroaromatics and aromatic amines are described in more detail here. In the the soil aromatic amines and nitrocompounds get into contact with the clay minerals and the organic matter via their nitro and amino groups. Anilines react as bases and are often present in protonated form, depending on the pH value. With decreasing pH value, increasing sorption to the mineral matter occurs because protonated amino groups are more strongly bound than the free bases. Anilines can form bonds with exchangeable protons of silicate surfaces or positively charged hydroxide surfaces. They react with hydrated exchangeable cations of silicates and can be indirectly bound via hydrogen bridges. They can also be coordinately bound by means of electron transfer [162]. In soils, aromatic amines are oxidized by free radicals, e.g., at the amino group. The reaction is catalyzed by clay minerals. Aromatic amines can form complex compounds with metals. At fairly high pH, pyridines and other compounds occur as neutral species and can then also bind to the organic matter. Ionic bonding to the soil matrix occurs especially when the pH of the soil is near the pK_a of the amine [163]. Pyridines can also be hydrophobically bound [164]. With few exceptions, the binding of aromatic amines and nitro compounds to the organic matter is only moderately strong (see Table 13). Pyridines [164], [166] and also nitro compounds [167] are therefore repeatedly found in mg/L quantities in the groundwater. Particularly in acid soils nitrobenzenes are reduced to anilines, by sulfides, especially by Na_2S in anaerobic soils [113].

Table 13. Degradation sorption and volatilization in % of pyridine (-derivatives) in soil suspensions after 30 d [165]

Pyridine (-derivatives)	Position	Bound	Degraded	Volatilized	Loss*
Pyridine		15.6	6.3	16	100
-OH	2,3-	2.4	<1		4
-COOH	2,3-	3.0	81		100
-CCl	2,3-	15.1	<1	50	79
$-NH_2$	2,3-	14.3	<1		4
$-CH_3$	2,6-	7.7	<1	23	29

* Indicates the recovery rate.

The nitrotoluene concentrations at a blasting site of a former explosives factory were in the mg/kg range and led to the closing of a drinking water well [168]. As follows from subsequent analyses, the concentrations clearly decreased (Table 14). Under anaerobic conditions a distinctly slower degradation occurs. A trinitrotoluene contamination of groundwater near Grand Island, Nebraska was also reported [167].

Table 14. Concentrations of nitrotoluenes in the surface soil of a blasting site near Torgau in µg/kg d.m. in 1992 as a function of time (data by the Regional Environmental Agency, Torgau)

	January	February	March	April	May	August	October
2,4-DNT [a]	390	18	n.d.*	96	n.d.*	<5	n.d.*

[a] DNT = dinitrotoluene.
[b] TNT = trinitrotoluene.
[c] DN-4-AT = dinitro-4-aminotoluene.
* n.d. = not detected.

The degradation of 2-nitroaniline and 4-nitrophenol was studied [169]. The bacterium *Nocardia sp*. can degrade these substances to 4-hydroxy-2-nitroaniline and nitrocatechol. The removal of a nitro or amino group associated with a hydroxylation has been observed with 2-nitrophenol, 4-chloroaniline, and 4-chloro-2-nitrophenol. An extremely slow degradation of chloroanilines by reductive dehalogenation by microorganisms under anaerobic aquifer conditions was observed [170]. Under methanogenic conditions the degradation rates were slightly greater (K < 0.01 – 1.36 after 8 months) than under sulfate-reducing conditions (K <0.01). The only exception was provided by 2,3,4-trichloroaniline, which was completely transformed after 10 months. Under some circumstances, pyridines are rapidly degraded; thus, e.g., pyridine itself is eliminated within 7 d [163]. However, also very persistent pyridine derivatives exist (Table 13), that frequently are also rather volatile. The differences between aerobic and anaerobic degradation are small. The persistence of the pyridine derivatives decreases in the following order: pyridinecarboxylic acid < pyridine = monohydroxypyridine < methylpyridines < aminopyridines = chloropyridines [165].

5.1.4.4. *Polychlorinated Dibenzodioxins (PCDDs) and Dibenzofurans (PCDFs)*

Dibenzodioxins and dibenzofurans are classes of aromatic ethers, with totals of 75 and 135 congeners, respectively. There are congeners substituted with 1 to 8 chlorine atoms (mono- to octachlorinated), which can also differ in the position of the chlorine atoms in the organic rings. Chlorine can be replaced by bromine, some substances can contain chlorine and bromine, so that finally 5020 different compounds of this type are possible. The toxicity of the dioxins and furans is rated by quoting a toxicity equivalent (TEQ) according to the BGA [171].

Chlorinated and/or brominated dibenzodioxins and dibenzofurans reach the environment mainly through thermal reactions (motor traffic, refuse incineration plants, industrial incinerators and blast furnaces, domestic heating systems, as byproducts of syntheses), etc. [172]. Also flame retardants that consist of bromine-containing phenols, benzenes, and biphenylene contain dibenzodioxins and -furans. Precursor compounds for chlorinated dibenzodioxins and dibenzofurans are chlorinated phenols, benzenes, polychlorinated biphenyls, and other aromatics in combination with oxygen and chlorine. Sulfur-containing octachlorodibenzodioxin (OCDD) analogues reach the environment via tire abrasion. Since dioxins and furans reach the environment mainly particle-bound or gaseous, degradation in the atmosphere is important. The hepta- and octachlorinated congeners especially are strongly bound and carried in the soil via dust particles or dust precipitation. The lower-chlorinated congeners seemingly undergo a more rapid photochemical degradation as a result of their higher vapor pressure. The annual PCDD/PCDF inputs to the environment of Germany, Sweden, Switzerland, and Norway have been estimated [173], [174]; inputs of ca. 0.928 kg (Germany), 0.14 – 0.82 kg (Sweden), 0.285 – 0.37 kg (Switzerland) and 0.430 kg (Norway) were determined. This calculation disregarded the large number of industrial blast furnaces and incineration plants with considerable PCDD/PCDF emissions. Only after these plants have been re-equipped can large reductions of the input be expected. At the end of the 1980s, 48 g of PCDD/PCDF were said to be introduced into soils annually through sewage sludges used in agriculture and amounts of the same order through liquid manure and composts (2.6 – 47 and 32 –80 g TEQ, respectively) [175]. Today the inputs are presumably distinctly less because the loads of sewage sludges and composts are no longer as high as in the 1970s or 1980s. Dioxin contents in surface waters of Hesse (the Main river) were 0.1 – 0.2 pg/L TEQ, in the corresponding suspended material 8 – 20 ng/kg d.m. TEQ, and in the sediments 9 – 19 ng/kg d.m. TEQ [176].

The immission air loads of rural regions are 0.025 to 0.07 pg TEQ/m^3, with a deposition of 5 – 20 pg TEQ m^{-2} d^{-1}. In urban regions the load is 0.07 – 0.35 pg TEQ/m^3 and 10 – 85 pg TEQ m^{-2} d^{-1}. In the neighborhood of emitters, immission values of 0.35 – 1.6 pg TEQ/m^3 and deposition values of ≤1000 pg TEQ m^{-2} d^{-1} are reached [177]. Loads in the rainwater (Dübendorf, Switzerland) were 0.03 – 0.1 and in mist 0.3 – 3 ng/L [97].

Viewed over time, the inputs of dioxins and furans to soils distinctly rose from 1920 and reached their maximum in the 1970s [178]. Studies in England on lake sediments show increases of dioxin since 1940 [179] (Fig. 16). Core drillings of lake sediment in Berlin indicate inputs falling overall by now.

Figure 16. Development of PCDD and PCDF contents in the surface soil of Rothamsted, United Kingdom [178]

The background load for soils was quoted as 0.8 ng TEQ/kg d.m. for Baden-Württemberg [180]. The contents in Bavaria are of a similar order [181]. Loads in urban areas and areas with greater industrial use are 3.4 and 8.4 ng TEQ/kg d.m., respectively [129]. On the other hand, the dioxin loads in North Rhine-Westphalia in rural areas were 0 – 10 ng/TEQ/kg d.m. (50 % < 5 ng TEQ/kg d.m.), and in the conurbations 10 – 15 ng TEQ/kg d.m. [99]. The dioxin load in forest soils reaches values of 50 – 80 ng TEQ/kg d.m. in the litter cover. Table 15 gives a compilation. The soils (0 to 5 cm) in the surroundings of metal works have distinctly higher loads (e.g., in Linz, Maulach, and Rastatt with up to 332 ng TEQ/kg d.m., 7926 ng TEQ/kg d.m., and 29 039 ng TEQ/kg d.m., respectively [150]. In the grassland young growth near such plants, 20 – 40 ng TEQ/kg d.m. were determined [182]. Correspondingly, increased dioxin loads were found in milk.

Table 15. Range of the dioxin loads of soils in Germany, compiled from data of the different states (situation at May 15, 1991; TEQ-calculation according to BGA [177])

Loaded area		Mean (ng/kg TEQ)	Range of the means	Minimum value	Maximum value	Number of samples	Sampling depth, cm

Because of the low water solubility and high lipophilicity of dioxins and furans, they are sorbed to the organic matter (Table 16). The K_{OC} values increase with increasing degree of chlorination, in this case from 10 000 to 57×10^6. Because of this strong sorption the higher-chlorinated congeners in particular have a low bioavailability and are nearly immobile in the soil. This is evident also in the congener distribution in soil, where the hexachloro- (HCDD) and octachlorodibenzodioxins (OCDD) dominate. The origin of the dioxins and furans can in some cases be deduced from the congener patterns. High proportions of octa- and hexachlorinated dioxins point to inputs from pentachlorophenol (PCP) sources.

Table 16. Sorption constants, water solubility (WS) and Henry's law constant of various dioxins

p-Dioxin	WS, µg/L	log k_d	log K_{OC}	log K_{OW}	Henry's law constant

* Calculated from log K_{OC} = 0.989 log K_{OW} – 0.346 [183].
** log K_{OW} of [184].

In a sandy-loamy silt, increased mobility of low-chlorinated dioxins (down to 40 cm depth) was observed over 12 months [185]. Deeper displacement of 2,3,7,8-tetrachloro-*p*-dioxin (2,3,7,8-TCDD) down to a depth of 5.40 m was determined at a contaminated site [186]. After the addition of lauryl sulfate and at pH values of 8 instead of 7, the K_{OC} fell by a factor 10. Such behavior of a substance can be influenced by cosolvents (e.g., oil) [187], [188].

Near the soil's surface (0.06 – 0.13 mm) the higher-chlorinated dioxins and furans in particular are subject to a photolysis at 250 – 360 nm [189], [190] and volatilization, that can be enhanced by solvents. Photodegradation and volatilization on plant surfaces can also contribute to the elimination of dioxins [191]. The degradation of dioxins and furans proceeds extremely slowly. The half-lifes vary from 10 – 14 years [192] to several decades. In other investigations scarcely any losses, but only small lateral displacements were found after 17 years [193-195].

The dichlorobenzofurans are less persistent than the dichlorobenzodioxins. While the degradation routes of the PCDDs have not yet been elucidated, microorganisms exist in polluted waters that can degrade dibenzofurans [196]. The organisms capable of degradation include *Pseudomonas spp*. [197]. The degradation of dibenzofuran leads after dehalogenation in an anaerobic environment finally to branched and unbranched paraffins [198]. Diphenyl ether, 2-methoxydiphenyl, and 2,3-dihydroxydibenzofuran are formed as intermediates. FORTNAGEL et al. [199] assume a primary degradation by *Pseudomonas sp*. *HH69*, in which 1-hydroxybenzo-*p*-dioxin is formed via an unstable dihydrodiol and after ring cleawage is degraded to 2,2,3-trihydroxybiphenyl which is transformed to catechol after a second cleavage. The inability of the microorganisms to degrade TCDD is a result of TCDD's high toxicity to microorganisms [200], its low ability to permeate membranes, its strong sorption, and its low water solubility or bioavailability.

Studies on the degradation of dioxins showed that succinate- and biphenyl-adapted microorganisms degrade monochlorinated dioxins because succinate and biphenyl bring about the enzyme induction required for this [201]. The relative conversion rate compared to biphenylene is >72 % for monochlorodibenzodioxin and 8.9 % for 1,2,4-trichlorodibenzodioxins. The degradation product is 1,2-dihydroxydibenzo-*p*-dioxin. In the case of more highly chlorinated dioxins a steric hindrance of the enzymes is to be expected. It is assumed that in the presence of other carbon sources (e.g., naphthalene, benzene, phenol) the microorganisms utilize these first. It can furthermore be assumed that the concentration range of the dioxins between enzyme induction and toxicity is very small. Furans are as a rule taken up in distinctly greater amounts than dioxins by soil-activating organisms or organisms living in the sediment [202]. The ovaries, liver, and intestine of *Fundulus heteroditus* (a species of fish) which take up higher amounts of dioxins provide an exception.

The estimation of the loading of the food chain by dioxins and furans plays a part in the determination of limit values. Over 90 % of the PCDD/PCDF uptake of humans occurs via food [203]. The dioxin uptake by dairy cattle, sheep, etc. as a result of polluted soils can amount to 10 % or more of the amount available in the soil. On average, 20 – 56 % of the dioxins absorbed by dairy cattle enter the milk [204]. Hexachlorodibenzodioxin is more rapidly metabolized than OCDD. Compared with other dioxins/furans, the 2,3,7,8-substituted tetra- and hexachlorinated dibenzodioxins and -furans are absorbed particularly in the milk and not mainly in adipose tissue of dairy cattle. The consumption of eggs is another source of PCDD/PCDF uptake by humans.

In rats 2,3,7,8-TCDD was 100 % bioavailable after transpulmonary uptake. The transfer factors via the air – plant path were estimated for leaf vegetable species to be 0.2 ng I-TEQ/kg d.m. (International Toxicity Equivalent Factor according to NATO-CCMS, 1988) [177], [205]. Deviations: green cabbage 0.4 ng I-TEQ/kg d.m.; pasture land 0.1 – 0.2 ng I-TEQ/kg d.m. A value of 0.01 ng I-TEQ/kg d.m. was assumed for the soil – plant transfer path. Such a definition often overlooks the fact that the transfer factors frequently vary just as strongly between the plant as between the plant species. The transfer of PCDD/PCDF via the water – sediment – fish path, is relatively high (30 % transfer). Thus the congener profile found in eels, for example, is reflected in that of the sediments.

Because of the enormous toxicity, the BGA has defined use-dependent limit values for soils [171], that do not, however, take account of the soil properties.

5.1.4.5. *Polycyclic Aromatic Hydrocarbons (PAHs)*

(⟶ Hydrocarbons, ⟶ Hydrocarbons – Toxicology and Occupational Health)

Polycyclic Aromatic hydrocarbons are formed during combustion processes (domestic heating, road traffic, fires, refineries, coking plants, waste incineration plants, etc.). They include a whole series of carcinogenic compounds. In all, there are assumed to be several hundred such PAHs. They enter the environment via the air, sewage water, and sewage sludges. Usually 18 PAHs in all are considered. On lands used for agriculture the contents of benzo[*a*]pyrene (BaP) were mainly <0.2 mg/kg d.m. and of fluoranthene <0.3 mg/kg d.m. soil [149]. In urban backyards and allotments, 10 – 20 % of the soils have contents of >1 mg BaP and >2 mg fluoranthene. In Bavaria, the concentration of six PAHs (fluoranthene; benzo[*b*]- and benzo[*k*]fluoranthene; benzo[*a*]pyrene, indeno[1,2,3-*c,d*]pyrene; and benzo[*g,h*]perylene) was determined in various soils [206]. The mean of the benzo[*a*]pyrene was a factor of ten higher than the reference value of 0.05 mg/kg d.m., and two soils out of twelve were above the B value (limit value for soil investigation [207]) of 1.0 mg/kg d.m. Soils in urban center areas are more heavily polluted. These areas consist in some cases of rubble and burnt building material and contaminated sites, such as gasworks. The total PAH load of soils frequently amounts to 10 times the BaP value.

With the exception of locally concentrated inputs, it is assumed today that PAH inputs into the soil occur mainly via the air path. Loads of PAHs (21 compounds) in Dübendorf (Switzerland) were 0.1 – 0.6 µg/L in the rain and up to 60 µg/L in the mist, with deposition rates of 10 – 60 and 90 ng cm^{-2} a^{-1} [97]. The annual increases in the soil of Rothamsted (United Kingdom), at 4.56 mg/m^2, were higher by a factor 2 – 3 [208] (see Fig. 17). Since the 1890s the concentration of PAH components in soil increased by the following factors: for benzo[*b*]fluoranthene, benzo[*k*]fluoranthene, and benzo[*a*]pyrene >15; for pyrene, benzo[*a*]fluoranthene, benzo[*e*]pyrene, and indenopyrene 10 – 15; for chrysene, benzo[*g,h,i*]pyrene, acenaphthylene, acenaphthene, 5 – 10; and for phenanthrene, anthracene, fluoranthene, and naphthalene, <5. Long-term sewage sludge application from 1940 to 1960 caused a remarkable increase of PAHs (see Fig. 18) compared to manured areas or the control area [208]. Since 1960 the PAHs contents have decreased gradually due to increasing quality of the sewage sludge.

Figure 17. Development of PAH contents in the surface soil of Rothamsted, United Kingdom [208]

Figure 18. PAH pollution of experimental soils fertilized by sewage sludge and of a soil treated with farmyard manure [208]

The strength of binding of the PAHs in the soil differs, depending on their water solubility. The K_{OC} values increase with the number of condensed benzene rings, and specifically from ca. log 2.8 to log 7 [209]. Because of the chemical structure of this class of compound, mainly hydrophobic bonding can be assumed.

The degradation proceeds very slowly in some cases [210]. The half-lifes in an arable soil vary for less condensed PAHs from 14 – 48 d and for more highly condensed PAHs from 603 to 2030 d, depending on the stability of the compound and its molecular mass (Table 17). The results of this study show that laboratory experiments permit conclusions on the behavior under natural conditions only to a very limited degree. In smoked soils the sorption is weaker and the degradation more rapid because the sorption is not yet at equilibrium. Bioavailable PAHs can be more rapidly degraded. In two soils treated in 1968 with sewage sludge rich in heavy metals, the half-lifes of PAHs were 2 – 9 a [211], i.e., degradation was impeded. The biological degradation is important in the case of naphthalene, which is degraded via the dihydrodiol to dihydroxynaphthalene and a hydroxybenzopyruvate derivative and finally via salicylic acid to catechol [124]. The degradation of phenanthrene is basically similar, although *o*-phthalic acid is cleaved in addition. Aside from *Pseudomonas spp.*, *Alcaligenes denitrificans* also is capable of degrading PAHs [212]. The more highly condensed PAHs (>4 rings) are considered to be extremely resistant to enzymatic degradation.

Table 17. Half-lifes (d) of various PAHs in soils from microcosm studies (losses in % in brackets) [200]

Compound	RA 1 [a]		RA 2 [b]		CF [c]		RS [d]		Mean SD	
	Soil	R^2 [e]	Soil	R^2 [e]	Soil	R^2 [e]	Soil	R^2 [e]

PAHs (total)	146	0.90	165	0.85*	192	0.79*	177	0.82	170	19.4

[a] RA 1 = rural arable soil, no preceding sewage sludge application.
[b] RA 2 = rural arable soil.
[c] CF = rural coniferous forest.
[d] RS = roadside soil.
[e] R^2 = linear regression.
* =significance.

According to studies the half-lifes of >4-ring PAHs exceed 300 d [213]. PAHs are not degraded under anaerobic conditions [170]. In addition to photolytic degradation and chemical oxidation, volatilization also plays a certain part during the elimination in and on soils. Simple PAHs, such as naphthalene and methylnaphthalene, volatilize in proportions of 20 – 30 %, and are also degraded abiotically to 2 – 20 %. Neither is true of more highly condensed compounds.

Analyses of grass samples since 1900 prove that the highest PAH values occurred between 1931 and 1935, whereas distinct reductions occurred after 1955.

The “light” PAHs stay largely in the gas phase and can be found in the leaves or parts of fruit, whereas the heavier ones remain in the soil [214] or root parts. They can therefore be found mainly on root surfaces, such as those of carrots [211]. Eleven years after the application of sewage sludge 30 µg ∑PAH/kg d.m. were found in potatoes. The light PAHs were dominant in sugar beets, beets, and carrots [215]. There is little indication that the contents of PAHs were raised by the sewage sludge in comparison with the control.

The mobility of PAHs in soils can be distinctly raised by increased sorption on the dissolved organic matter. It has been that naphthalene and other PAHs can be displaced in the order in which they are bound to dissolved organic matter (DOM) [107]. From 100 mg/L DOM, hydrophobic substances with K_{OW} values $>10^{4.5}$ can be transported at the same rate as the dissolved organic matter. Under aquifer conditions, the mobility of the mobile phase of a PAH-containing coal tar in sandy material amounted to barely 7 cm in 54 d ca. 14 % of the naphthalene, 0.2 % of the fluoranthene and 0.06 % of the benzo[*a*]anthracene having been transformed in 91 d [216]. The transport is attributed essentially to molecular diffusion.

5.1.4.6. *Polychlorinated Biphenyls (PCBs)*

Polychlorinated biphenyls can occur in 209 congeners. About 60 individual substances with chlorine contents between 21 and 68 % have been detected. PCBs have a very low water solubility and are chemically very stable. They are therefore detected ubiquitously. About 2×10^6 t of PCBs have been produced worldwide since 1929, but they can also occur as byproducts in organic syntheses and in the pyrolysis of chlorobenzene. The coplanar PCBs 77, 120, and 169 have proved to be more toxic than the nonplanar *ortho*-substituted PCBs. PCBs are present in used oil, condensers, adhesive and sealing compounds, chipboards, ceiling panels, flame retardants, hydraulic fluids, films (as plasticizers), etc., but an extensive ban has existed on their use for open systems, in the Federal Republic of Germany since 1972 and EC-wide since 1985.

Wide-area pollution occurs mainly via the air path. In conurbations, 180 g km^{-2} a^{-1} of wet and dry deposition of PCBs is assumed. Low-chlorinated congeners distributed more by the gas phase, and high-chlorinated ones are mainly distributed particle-bound. According to CAPEL et al., PCBs (31 compounds) can be discharged at 7 – 22 µg/L in the mist and 0.002 – 0.003 µg/L in the rain, which results in a deposition of ca. 110 –330 g km^{-2} a^{-1} [97].

Municipal sewage sludges contain 0.1 – 1.0 mg/kg d.m. [105] and river sediments 0.01 – 1.0 mg/kg d.m. of PCBs. The 90 % percentile values are about 4.8 µg/kg d.m. for rural areas (grassland) and ca. 15.5 µg/kg d.m. of PCBs (13 congeners) for conurbations. The three coplanar PCBs usually amount to 10 % of the whole. The PCB contents were raised by a factor 10 – 15 especially in the flooded area of the Rhine [99]. In forest soils, the mean PCB content in the humus cover was ca. 85 µg/kg d.m. The contents in the subsoil were as high as in the surface soil [176].

PCBs are bound in soils as a function of their water solubility and lipophilicity, i.e., sorption increases from the singly chlorinated to the polychlorinated biphenylene. The K_{OC} values rise from 10^3 to 8×10^5 (see Table 18). At low humus contents, the content of clay and allophanes is also important in PCB sorption [288].

Table 18. Physicochemical data of PCBs

Biphenyl	IUPAC, No.	WS, mg/L	K_{OC}*	k_d**
Biphenyl		7.5	1400	
2-Chloro-	6	0.062	4460 – 7940	
4,4′-Dichloro-	15	0.062	20 000 – 100 000	
2,4-Dichloro-	20		151 000	7 – 20
2,4,4-Trichloro-	28	0.113	166 000	
2,2,5,5′-Tetrachloro-	52	0.113	257 000	21
2,2,4,4′-Tetrachloro-		0.085	17 000	
2,2′,3′,4,5-Pentachloro-	87	0.099	490 000	740
2,2′,4,5,5′-Pentachloro-	101	0.029	425 000	810
2,2′,3,4,4′,5-Hexachloro-	138		70 800	2420
2,2′,4,4′,5,5′-Hexachloro-	153	0.001	724 000	2500
2,2′,3,4,4′,5,5-Heptachloro-	180		794 000	4640
2,2,3,4,4,4′,5,6-Heptachloro-	183	0.00047	620 000	3620
2,2′,3,3′,4,5,5′,6-Octachloro-	201			8700

* [217], low clay contents.
** [218], low humus contents.

The degradation of PCBs in soils under aerobic conditions proceeds slowly, and under anaerobic conditions very slowly [219]. Anaerobic degradation occurs as a reductive dehalogenation. After input over many years, the hepta- and octachlorinated compounds accumulate, because of extremely small degradation and more powerful sorption than the low-chlorinated compounds [150]. After 300 d no reduction of PCBs was found in soils treated with sewage sludge [220]. In other field experiments only after application of 50 t sewage sludge per hectare was a five- to seventeenfold enrichment observed, a value of 0.05 mg/kg d.m. not being exceeded [221]. Mono- and dichlorinated PCBs degrade microbially, e.g., by *Achromobacter* or *Pseudomonas spp.* to benzoic acid via the dihydrodiol and *meta* cleavage of the rings.

With increasing chlorination, the degradation proceeds more slowly, especially if a chlorine atom occupies a position *ortho* to the second ring [222]. The volatilization of low-chlorinated PCBs is regarded as a possibility of elimination, especially because of their great persistence [223]. Aroclor 1254 was released from the soil by 40 – 50 % within 2 – 4 months. Hexa- and heptachlorobiphenyls were released only half as well as trichlorobiphenyl.

In case of high PCB pollution and long-term action, PCBs can reach even deep soil layers and the groundwater (distance from ground elevation: 1 – 1.2 m). The migration depends on the solubility of the PCB [224]. If used oils or an oil phase are present in the underground, PCBs can also move laterally. The greater solubility of PCBs in the oil phase than in the dissolved organic matter causes a tenfold enrichment in the oil phase [225].

For many applications (e.g., risk assessment) it is necessary to estimate the behavior of PCBs and other pollutants in soil. For landscape planning, for groundwater protection, for sewage sludge application on farmland, etc. a site-specific prediction system to evaluate the behavior of such pollutants is important for the administration to protect the environment. Results from field trials with more than ten different soil types are in good agreement with estimates obtained for a qualitative evaluation [226].

PCBs are absorbed by plants only in small amounts. Studies with soils treated with sewage sludge containing PCBs showed that carrots in particular, because of their lipoid-containing roots, accumulated PCBs in their skin [227]. The bioconcentration factors (⟶ Ecology and Ecotoxicology – Bioconcentration, Bioaccumulation, and Ecological Magnification) were: in the roots, 0.02 – 0.04; in the skin, 0.02 – 0.1; and into the foliage, <0.002 – 0.0008. The low-chlorinated congeners in particular are absorbed. Small uptakes were also determined in various grasses, grains, and vegetable species [221]. The bioconcentration factors were between 0.2 and 0.02. The action of PCBs in other useful plants was also studied [228]. At PCB concentrations above 10 000 mg/kg d.m., growth inhibition was established in soya and beets. No metabolization and only minor xylene transport was found [229]. Only 20 – 25 % of PCBs absorbed by rats via the soil was not excreted. Different soil properties scarcely affected the excretion.

Within an animal food chain (oak leaves, earthworm, great tit's egg) an accumulation (biomagnification) of 1 ng/g to 170 ng/g of PCB 153 occurred [230].

5.2. Acid Precipitation

5.2.1. *Definitions*

Used in a strict sense, the term acid precipitation is defined as increased hydrogen ion content of precipitation water due to anthropogenic sources [231]. From a chemical point of view this term must be extended, and other rain components included that are subject to acid – base reactions after deposition. As a consequence of these reactions, hydrogen ions may be generated when rain water comes into contact with vegetation and soil surfaces. The term “potential acidity” therefore takes into account all acidic components carried in atmospheric deposition fluxes.

Meteorology distinguishes different forms of atmospheric deposition such as rain, snow, dry particulates, aerosols, gases. Assessment of deposition fluxes and separation of single fluxes are very difficult to accomplish for methodological reasons [232]. Nevertheless, in order to estimate effects of acid precipitation on soils and ecosystems, assessment of all forms of atmospheric deposition is indispensable.

With regard to the impact of acid deposition on soils, it is also necessary to define the terms acidity and acidification for soils, soil water, groundwater, and surface water. *Soil acidity* is usually expressed as the hydrogen ion activity (pH) measured in an aqueous suspension of a soil sample. The pH is a key parameter for most soil-chemical reactions and for the conditions in which soil organisms live and plant roots are growing. However, pH is an intensity parameter which gives no information on the extent to which acid – base reactions can be maintained in a given soil over time. Therefore, when soil changes in time are considered soil acidity must be described using capacity parameters (such as mass of acids and bases available in the surface soil layers).

According to [233], *soil acidification* is related to (1) a decrease in acid neutralizing capacity (ANC, common units mol H^+ per kilogram soil or per square meter of a defined soil horizon) of the soil by loss of base cations such as Ca^{2+}, Mg^{2+}, and K^+, and/or (2) an increase in base neutralizing capacity by retention and accumulation of H^+ and acid cations such as Al [Al^{3+}, $Al(OH)^{2+}$, $Al(OH)_2^+$] and heavy-metal ions. These changes are accompanied with a decrease in soil pH when the acid strength of the acidic groups of the solid phase in the soil increases. Acidification may take place in one or more soil horizons, depending on the balance between acid input (or production) and acid output (or consumption).

In soil water, groundwater, and surface water chemistry, acid – base conditions are usually described in terms of alkalinity. Alkalinity can be defined as the sum of

$$2\left[CO_3^{2-}\right] + \left[HCO_3^-\right] + \left[OH^-\right] - \left[H^+\right] - 3\left[Al^{3+}\right] - 2\left[Al(OH)^{2+}\right] + \left[Al(OH)_2^+\right]$$

where brackets denote molar concentrations of each ion species [234]. Alkalinity defined in this way may take positive or negative values. Water acidification is then defined as a loss in alkalinity.

Thus, the choice of appropriate parameters to characterize acidity of precipitation in relation to its effects on soils and ecosystems depends on the time scale in which the impact of acid deposition is considered. Processes occurring in the soil can be classified into different categories, *direct* and *long-term processes.* The first category of processes is directly and instantaneously related to acid intensity. Examples for such processes are: dissolution of solid mineral phase, ion exchange on mineral particles and humic substances, formation and destruction of ionic complexes and, as a consequence, toxic effects on soil organisms and plant roots. These processes instantaneously follow changes in thermodynamic conditions at any given point of the soil or ecosystem. Here acidity influences soil-chemical processes which may be connected to life processes on the organism or ecosystem level, but must not necessarily have any visible effects on soil components (soil minerals, aggregates, humus). For these processes acidity is appropriately described by the pH of solution. The presence of cation acids and the redox potential may be additional conditions to be considered.

The second category of acidity-related soil processes becomes important in long-term considerations. As a result of this type of processes, changes in composition and structure of soil minerals and soil organic matter, in nutrient availability, and soil biology are observed, followed by changes on the ecosystem level (changes in tree population, plant, and animal

communities). The underlying processes — acid – base and redox reactions — are the same as those described in the first category and are occurring naturally in soils. Acid impact often results in an acceleration and intensification of natural processes such as weathering and alteration of minerals, leaching of nutrient cations, aluminum, iron, and manganese, depletion of the exchange complex, formation of secondary minerals, redistribution of elements in the soil profile, build-up of organic matter at the soil surface, retreat of roots from deeper soil layers, changes in the edaphon (soil animals) and in the herb layer. All these changes tend to be irreversible at least within a human life span. In contrast to the first category, these processes result in visible changes in the structure and composition of soil itself. In order to characterize acid deposition with respect to the described effects, capacity parameters such as deposition, capacity parameters such as deposition fluxes of acidic substances (expressed in ion equivalent per unit surface and time, e.g., meq m^{-2} a^{-1}) are appropriate.

5.2.2. *Sources of Acidity in Atmospheric Deposition*

Most acidic components of atmospheric deposition may originate both from natural and from anthropogenic sources. In order to justify control measures for soil protection and to set priorities, it is necessary to quantify the contribution of single sources of acidity, natural as well as anthropogenic.

Table 19 shows substances which form protons in cloud droplets and precipitation water, or which carry acidity into soil. The substances are listed together with their most important sources. In industrialized countries, carbonic acid (1) and strong mineral acids (2) are generally the most important contributors to precipitation acidity, the acid intensity (pH of precipitations; see below) being determined mainly by (2). In class (2), man-made sources by far exceed natural sources, at least in the industrialized countries of the northern hemisphere [231]. Ammonium (3) plays an important role in areas with intensive agriculture mainly with a high density of livestock. Hydrosulfuric acid (4) and its oxidation products may be important contributors to acidity in bogs, swamps, and on mangrove coasts. Organic and cation acids [substances (5) and (6)] are usually of minor importance in precipitation chemistry.

Table 19. Acidic components of atmospheric deposition and their main sources

Substances	Anthropogenic sources	Natural sources
(1) CO_2 and H_2CO_3	combustion of fossil fuels	atmospheric CO_2, respiration, mineralization of organic matter
(2) Strong mineral acids and their precursors		
SO_2 and H_2SO_4	combustion of fossil fuels, incineration, smelting of ores	volcanic exhalation
NO_x and HNO_3	combustion of gasoline, agriculture (livestock)	electric discharge (lightning), microbial denitrification in soils, forest and grassland fires
HCl_{gas}	incineration of refuse, chemical industry	
(3) NH_4^+, when transformed into ammonia or when taken up by organisms to form organic N-compounds	agriculture, sewage treatment, chemical industry	decomposition of organic N-compounds (proteins)
(4) H_2S	chemical industry	biogenic emissions from marine algae and sulfate-reducing bacteria
(5) Organic acids	chemical industry	
(6) Cation acids (as Al^{3+}, heavy metals)	soil and industrial dust particles when dissolved in acid precipitation	soil particles when dissolved in acid precipitation

The rate of deposition of acidic components varies in a wide range, depending upon local pollution situation, exposition, and surface characteristics. Mean annual desposition rates in Germany were around 270 meq m^{-2} a^{-1} on average, with values between 80 in the southwest, and 1000 in the eastern part of the country in 1993 [237]. About 60 % of the total is made up of sulfuric oxides. As a consequence of technical measures to reduce acid deposition from the atmosphere, deposition rates of sulfur compounds have been gradually reduced in the 1980s. Nitrogen deposition does not show this trend [237], [238].

As pointed out above, when impact of acid deposition on soils is studied, alkaline components of precipitation must be taken into account. The most important basic components are listed in Table 20, together with their sources.

Table 20. Components contributing basicity to atmospheric deposition and their main sources

Substances	Anthropogenic sources	Natural sources
(1) HCO_3^-	see (1), Table 19	see (1), Table 19
(2) NO_3^-, when taken up by organisms to form organic N-compounds	see NO_x in (2), Table 19	see NO_x in (2), Table 19
(3) NH_3, when transformed to ammonium NH_4^+ (see Table 19)	agriculture (livestock)	decomposition of organic matter (proteins)
(4) dust particles from limestone and other carbonates	cement industry, agriculture	soil dust

5.2.3. *Source and Sink Processes for Acidity in the Atmosphere and in the Soil Environment*

For the effect of acid deposition on soils it is unimportant whether the hydrogen ions are already present in the cloud droplet or in precipitation, or are generated by chemical reaction of a pollutant at vegetation surfaces or in the soil. Chemical reactions not only depend on presence and amount of reaction agents, but also on thermodynamic conditions at the site of reaction. Therefore, in order to understand the effects these conditions must be specified. The most important variable in acid – base reactions is the pH at the site of reaction, but other factors such as redox potential or temperature must also be taken into account.

Source processes are listed in Table 21 together with the range of physicochemical conditions — in a generalized form — under which they take place. Under these conditions atmospheric substances undergo chemical transformation (indicated by an arrow), generating hydrogen ions in the atmosphere (cloud droplets, precipitation water), at the contact of rain with surfaces (vegetation, soil), or in soil water.

Table 21. Hydrogen ions generation processes in atmosphere and in soil

Process	Conditions
(1) Formation of carbonic acid from carbon dioxide originating	
in atmosphere: from atmospheric CO_2	
in soil: from soil respiration	
$CO_2 + H_2O \longrightarrow H_2CO_3 \longrightarrow H^+ + HCO_3^-$	pH >5.0
(2) Formation of strong mineral acids	
$SO_2 + 1/2\ O_2 \longrightarrow SO_3 \longrightarrow H_2SO_4 \longrightarrow 2\ H^+ + SO_4^{2-}$	independent of pH; oxidizing conditions with an oxygen source (free atmosphere)
$NO_2 + H_2O \longrightarrow HNO_3 \longrightarrow H^+ + NO_3^-$	independent of pH
$HCl_{gas} \longrightarrow H^+ + Cl^-$	independent of pH
$H_2S + 3/2\ O_2 \longrightarrow H_2O + SO_2$ (see Table 19)	oxidizing conditions
nitrification $N_{org} \longrightarrow HNO_3$ (see Table 19)	oxidizing conditions
$NH_4^+ \longrightarrow HNO_3$ (see Table 19)	
(4) Formation of organic acids	presence of organic matter and soil microorganisms
(5) Hydrolysis/protonation of weak metal hydroxides, e.g., $Al^{3+} + H_2O \longrightarrow Al(OH)^{2+} + H^+$	pH >4

(6) Formation of biomass by uptake of nutrient cations (most important: ammonium)	

Finally, Table 22 gives a list of *sink processes* which consume hydrogen ions, thus neutralizing acidity.

Table 22. Hydrogen ion consumption processes in atmosphere and in soil

Process	Conditions
(1) Transformation of bicarbonate into carbonic acid $HCO_3^- + H^+ \longrightarrow H_2CO_3$	pH <5
(2) Dissolution of carbonates $CaCO_3 + H^+ \longrightarrow Ca^{2+} + HCO_3^-$	
(3) Weathering of silicates	
(4) H^+ exchange on cell walls of leaf surface and on the exchange complex of the soil against (base) cations	
(5) Weathering of clay minerals	
(6) Formation of biomass by uptake of nutrient anions (most important: nitrate)	
(7) Transformation of ammonia into ammonium $NH_3 + H^+ \longrightarrow NH_4^+$	pH >6.5

5.2.4. *Direct Effects of Acid Deposition on Soils*

Traditionally, direct effects are studied separately for different environment compartments, such as vegetation cover, soils, subsoils, groundwater bodies, lakes, buildings, etc. In landscapes subject to acidic deposition, chemical reactions occurring at any point are interrelated, mostly by fluxes of water and dissolved matter, but also by transfer in the solid and gaseous phase, or by organisms. The ecosystem approach helps to find the linkage between individual processes, and to close the gap of understanding between chemical characterization of acid rain and damage to the environment.

When precipitation reaches the soil, acids or acidifying components usually undergo chemical reactions with the soil matrix which is not in a (chemical) equilibrium with rain water. The kind of reaction and the effect of acid input depend very much on type of soil and underlying bedrock. It has been suggested to group soil types according to criteria which reflect the type of buffering system in effect, and its buffering capacity [235].

In soils on calcareous bedrocks that are not totally decalcified and contain rather unweathered lime particles in the surface horizons, acidity is readily neutralized by weathering of carbonates, resulting in the release and leaching of Ca^{2+} with seepage water to the subsoil, together with bicarbonate [reaction (2) in Table 22]. This reaction is usually fast enough to buffer even high atmospheric input of acids. Only if limestone is distributed very disproportionate over the soil volume, even this soil type may acidify in the fine fraction of upper soil layers.

In soils free of limestone the weathering of primary silicates leads to the release of base cations such as Na^+, K^+, Mg^{2+} and Ca^{2+}, which then buffer the protons [reaction (3) in Table 22]. The consequence is again cation loss by leaching, soil is depleted from essential plant nutrients. The rate of silicate weathering depends on contents, type, and grain size of silicates in the mineral fraction of soil. The rate is estimated to range between 20 (soils on sandy sediments, sandstone, quartzitic bedrocks) and 200 (soils on basaltic rock) meq m^{-2} a^{-1} for a soil depth of 1 m [239]. These figures represent the maximum proton consumption rate. In comparison, the acid load from atmospheric deposition is 50 to 600 meq $m^{-2}a^{-1}$ [240].

In cases where acid deposition exceeds silicate weathering rate, or when silicate content in mineral soil is low or zero (sandy soils, soils on acid loess loam, quartzitic bedrocks), protons are neutralized by displacement of exchangeably bound Ca^{2+} and Mg^{2+} from the surfaces of clay minerals, iron and manganese oxides, and humic matter [reaction (4) in Table 22]. As a consequence, soil suffers further leaching losses of plant nutrients. The total ANC of the exchange complex in the rooting zone of vegetation ranges between 0.7 (acid sandy soils) and 70 eq/m^2 (well-buffered clay soils). Comparing these figures with total acid input during a 10-year period of 0.5 – 6 eq/m^2 (see above) it is obvious that acid input may lead to a complete depletion of the exchange complex on less-buffered soils within a short period of time. This depletion is reversible after a decrease in acid load from atmospheric input, but at low weathering rates (see above) complete recovery may require decades or centuries.

When the ANC decreases because of leaching of buffering substances to deeper soil layers, protons begin to attack the crystal lattice of clay minerals at pH <4.2 [reaction (5) in Table 22]. The consumption of protons is then balanced by release of cation acids (mainly monomeric or polymeric Al ions) from the clay minerals which, in turn, tend to displace base cations from exchange sites. Saturation of the exchange complex with Al ions is followed by an increase of Al and heavy metal ions in soil solution. This process is ecologically harmful because Al and most heavy metal ions are toxic in their ionic form for plant roots and soil microorganisms [241], and acidification of subsoil and groundwater is promoted with leaching of these cation acids to deeper soil layers.

When the exchange sites are saturated with Al ions, the concentration of Al ions in soil solution is mainly determined by the concentration of sulfate, which is usually the dominant anion in acid soils in regions subject to acid precipitation. Under these conditions aluminum hydroxosulfates are formed and accumulate in acidified soil horizons [242]. These sulfates have to be considered as a quite labile pool of cation acids, which is readily mobilized under changing chemical conditions in the soil (lowering of pH), and then may be carried to deeper soil layers or groundwater with seepage water.

5.2.5. *Effects Mediated by Organisms (Indirect Effects)*

Indirect effects are mediated by organisms, mainly through plant roots and microorganisms. In such cases, atmospheric input of acidic components initiates processes which produce acidity and transmit it to the soil. This gives rise to further soil acidification with reactions described in Section Direct Effects of Acid Deposition on Soils.

5.2.5.1. *Soil Acidification by Canopy Leaching*

When acid precipitation hits vegetation, hydrogen ions may be buffered on leaf surfaces by exchange with Ca^{2+} or Mg^{2+} bound to acidic groups in the cell walls (reaction (4) in Table 22) [243], [244]. The basicity used up for neutralization of atmospheric acidity must be replenished from the exchangeable pool of Ca^{2+} and Mg^{2+} in the soil. Consequently, soil is acidified by this process and its ANC decreases. Such effects are predominantly observed on slightly acid soils in the main rooting zone of the trees (B horizon). Surface soil (A horizon) and organic surface layer (O horizon), which receive base cations from canopy leaching and litterfall, remain in a state of high base saturation. This shows how acid deposition reaches soil via root surfaces. Buffering in the canopy does not prevent the soil being acidified in the rhizosphere within very short time.

5.2.5.2. *Acidification by Uptake of Nitrogen Compounds*

Atmospheric deposition of nitrogen compounds occurs mainly in the form of nitrate and ammonia. The plants usually take up these compounds wholly or partially, nitrogen being one of the most important plant nutrients. The uptake of nitrate by organisms and transformation into organic molecules results in the equivalent consumption of protons (reaction (2) in Table 20).

In contrast, if ammonium (NH_4^+) is taken up to form organic nitrogen compounds, an equivalent amount of protons is generated [Table 19, reaction (3)]. If nitrate and ammonium are taken up in equivalent amounts, consumption and production of protons are balanced and no net acidification takes place. But when ammonium is deposited in excess, as in the vicinity of intensive agriculture (livestock), and is taken up by plants or transformed to nitrate and leached, this results in a considerable acidification of the soil horizon in which ammonium uptake is located.

5.2.5.3. *Acidification by Accumulation of Organic Matter*

The emission of nitrogen oxides (from industrial processes and combustion of oil and gasoline) and of ammonia (mainly from intensive agriculture/livestock) leads to considerable deposition of nitrogen compounds on large areas (20 – >50 kg N ha^{-1} a^{-1}). In many forests on poor soils, nitrogen would represent a minimum factor in the nutritional supply of the trees without this input. The consequence of nitrogen deposition is an enhancement of tree growth and accumulation of biomass and litter at the soil surface. During the buildup phase of this pool of biomass, these processes result in a depletion of the mineral soil from nutrients (Ca, Mg, K), and a decrease of buffering capacity in the root zone, connected with a temporary or permanent acidification of the root zone.

Another effect of soil acidification is the inhibition of mineralization of litter and other forms of dead organic matter. In forests, an organic layer is built up at the soil surface, in which the activities of soil animals are reduced, and the microorganism population shifts from a dominance of bacteria to one of fungi. The mineral horizons underlying the organic surface layer are subject to intensified podzolization, with leaching of base cations, low-molecular organic matter and metal ions (Al, Fe, Mn) in complex form. In shallow soils, this can result in

groundwater and surface water acidification.

5.2.5.4. *Acidification by Humus Disintegration*

Forests on well buffered, noncalcareous soils, e.g., on basaltic rocks under deciduous forests in favorable climatic conditions, usually show a soil profile with a deeply developed A horizon very rich in humus. The amounts of nitrogen stored in the organic fraction of such soils may be considerable. Under the conditions of high acid input, these stores of organic matter tend to disintegrate, i.e., the buildup of new humic substances is delayed (possibly through inhibition by Al ions) compared with the mineralization through accelerated degradation of high polymeric humic substances [245]. As a consequence of humus disintegration, the organically bound stores of nitrogen are transformed into nitrate (nitrification by soil bacteria). If the nitrates thus formed are not taken up by roots or soil organisms, but are leached with seepage water, a considerable acidification of the soil according to reaction (2), Table 21, results. This effect may be estimated by keeping in mind that a loss of 1000 kg N by nitrification and leaching would be equivalent to 7 eq/m^2. The same process, however, may also lead to the release of gaseous nitrous oxides, mainly NO, into the atmosphere [246], hereby not only avoiding the release of protons to soil solution, but returning to the atmosphere a gaseous component which is acidic (Table 19) and is relevant with respect to the "greenhouse effect". This example elucidates the complexity of acid-base-processes in the soil environment which can only be understood as part of functional relationships between ecosystems. It makes the distinction between direct and indirect effects to be rather artificial one.

5.2.6. *Consequences of Soil Acidification*

The most important consequences of soil acidification for structure and function of soil itself, for the ecosystem of which soil is part, and for adjacent systems such as groundwater, lakes, and rivers are summarized below:

1. Loss of plant nutrients by enhanced leaching of basic cations which function as buffering against acidity — as secondary effects disturbance in the nutrition of trees and other plants, destabilization of forest ecosystems
2. Mobilization of cation acids, mainly Al and heavy metal ions from native soil minerals and/or atmospheric pollutants accumulated in the upper soil layers — as secondary effects toxicity to fine roots of trees and other forest vegetation, to soil animals and microorganisms, destabilization of forest ecosystems
3. Acidification of subsoil, underlying bedrock, groundwater and surface water, and concentration increase of undesired or toxic ions (nitrate, Al and heavy-metal ions) in the water
4. Formation of dissolved organic matter [247] which may interfere in many ways with inorganic components, thus making the judgement of acdifying effects upon hydrosphere very difficult.

5.2.7. *Field Observations of Soil Acidification*

Since the beginning of industrialization of Western Europe, and more intensively from the 1950s onward, soil acidification has increased progressively. This is indicated by a number of studies, refering to different interrelated acidification parameters (see Sections Definitions, Sources of Acidity in Atmospheric Deposition, Source and Sink Processes for Acidity in the Atmosphere and in the Soil Environment, Direct Effects of Acid Deposition on Soils, Effects Mediated by Organisms (Indirect Effects), Consequences of Soil Acidification).

Decrease of Soil pH. The earliest widespread pH measurements in forest soils were made in the late 1920s. These data were reexamined in 1978 [248]. Comparison with new measurements suggests that strong soil acidification has occurred in areas close to industrial zones and on mountain ridges with high acid atmospheric deposition. Soil acidification in soils under new planted spruce stands is attributed to ecosystem-internal acidification. pH measurements were repeated in a forest soil inventory in Bavaria after 20 – 30 a [249]. Depending on the initial acidity status, a decrease in soil pH of 0.3 to 1.8 units was observed on almost 50 % of 1000 cases. A review of soil pH changes found in a number of European countries is given in [250]. BERDEN et al. 1987 critically reviewed pH and base saturation data from Scandinavian and Central European forest soil samples since the 1940s, resampled after 20 to 50 years [251]. The drop in pH after this time span decreases, as expected, with decreasing pH at the time of first sampling. Similar results are reported for North Rhine-Westphalia, which suggest acid deposition as cause for soil acidification in the 1960s –1980s [252]. A good correlation was found between acidification parameters in soils and exposition of the site resulting in very different atmospheric deposition rates. Further evidence for soil pH decrease under forest vegetation is given for the Berlin region [253], mountain areas of North Rhine-Westphalia [254] Hesse [255], and the Hamburg region [256].

Decrease in Exchangeable Bases (Ca and Mg) and Base Saturation. In forest soils in North Rhine-Westphalia the exchangeable Ca has decreased by about 50 % since the 1950s [257]. In 1987 an average of 50 % decrease in base cation stores was found in Swedish forest soils since the 1970s to 1950s [258]. Similar results were found for the Harz [259], the Oberpfalz [260], [261], and South Sweden [262] and in a large scale survey of forest ecosystems in Western Germany [263] . A large number of field studies showed increased soil acidification around the trunks of beech trees, where large amounts of stemflow with high acid load infiltrates the soil [264-267]. Beech stands in remote areas of Southern Europe that are little influenced by acid deposition do not show this pattern [268].

Increase of Protons and Cation Acids at the Exchange Complex [269], [270]. For south Swedish forest soils an increase in the pool of exchangeable Al of 100 % was shown [262].

The appearance of cationic acids, mainly ionic species of Al, in groundwaters and surface waters as a consequence of soil acidification was reported in many studies, for example, in forest-covered Central German mountain areas such as Kaufunger Wald [271], Harz [259], [272], Hesse [273], Fichtelgebirge [274]. For a review, see [275], [276]. Distinction between naturally occurring acidification of ground- and surface water and acidification caused by atmospheric deposition is usually made by using sulfate concentration as indicator (mobile anion concept, see [234]). When sulfate becomes the dominant anion in solution, the cause for acidification is attributed to atmospheric input, provided the underlying bedrock does not contain sulfate or sulfide minerals. In the mountains of the Harz (Lower Saxony), rivers and creeks of different acidification types exist in close vicinity, depending on acid load from atmospheric deposition and types of soil and bedrock [277], [278].

Reversibility of Soil Changes. The undesired effects of soil acidification are traditionally avoided in agriculture by liming. Due to the progressive acidification of forest soils in the last decades, liming has become common practice in forestry on soils with high atmospheric acid input and low base saturation [279]. This is done in order to improve forest nutrition and nutrient turnover as well as to protect hydrosphere from the input of potentially toxic ions with seepage water. On the other hand, great efforts have been made to reduce acidity in the atmosphere by legislative measures, mainly directed towards control of sulfur and nitrogen emissions from combustion of fossil fuels and refuse. Related to ecosystem research, investigation of the ability of ecosystems to recover from the negative effects has become an important topic. This found its expression in "clean rain roof experiments" in different countries, in which forest ecosystems have been excluded from acid deposition impact, observing the change in acidity parameters and recovery of plant and animal communities [280], [281].

5.3. Fertilizers and Agricultural Chemicals

5.3.1. *Fertilizers*

5.3.1.1. *Development of Fertilization*

The development of fertilization in the 20th century is marked by an increased production of manures and a large rise in the consumption of inorganic fertilizers. From the beginning of the century until the mid-1980s, the use of nutrients in Germany in agriculture developed as follows: Inorganic fertilizers increased from a few kg/ha to an average of 130 kg N, 65 kg P_2O_5 and 90 kg K_2O per hectare of agricultural areas. In the 1980s the annual consumption of manures of animal origin was 100 kg N, 60 kg P_2O_5, and 110 kg K_2O per hectare [282]. In Germany, for example, from 1985 to 1997 the annual consumption of inorganic fertilizers fell to 101 kg/ha N, 24 kg/ha P_2O_5, and 37 kg/ha K_2O [283]. Similar results are reported for The Netherlands and the United Kingdom, whereas a much lower reduction is found in southern Europe. The major causes of this decline in Germany were the reorganization of the agricultural market ordinance (reduction of selling prices to world market level, payment of land grants), structural change, and the increasingly selective use of manures. These and other causes (limitation of the amounts of fertilizers by legislation, smaller nutrient losses and greater utilization of the fertilizers, higher fertilizer prices in combination with decreasing selling prices of agricultural products, increase of ecological farming with abandonment of the use of fast-acting inorganic fertilizers, declaration of water protection and conservation areas) will have the effect that the trend, of a declining use of inorganic fertilizers with simultaneously more selective use of the manures will also continue, in weakened form, in future.

Because of the use of composts and of secondary raw material fertilizers (e.g., sewage sludge), an additional input of nutrient into soils will occur in future. While the proponents consider this a possibility of closing the nutrient cycle of nature to the greatest possible extent and of dispensing with the feeding of inorganic fertilizers, critics fear a contamination of the soil by heavy metals and organic pollutants.

5.3.1.2. *Legal Framework of Fertilization*

In many countries, especially in the EU, fertilization is governed by various laws and regulations. First of all users have to prevent damage to the environment as a result of improper use of fertilizer. But during the 1990s the regulation of fertilization was discussed in another context: To what extent can the possibility of lasting cultivation of the soil and land be guaranteed as it is demanded by the AGENDA 21? In terms of long-term effects fertilization can have favorable as well as negative effects, therefore it is the responsibility of government and science to come to balanced conclusions. In some countries support and subsidies are provided for farmers to comply with special restrictions of fertilization.

In Germany all laws and regulations affecting fertilization were amended or reenacted during recent years. This fact reflects the increased attention of society to the application of substances to soil. As an example the essential contents and objectives of the German laws and regulations are described below.

The fertilizer law (Düngemittelgesetz, DümiG of November 15, 1977, last amended by law on December 17, 1999) defines fertilizers and thereby lays down what substances may be applied to agricultural lands. Beyond that the law governs the application of fertilizers and defines the expression "fertilization according to good technical practice" as follows: "The fertilization must be directed, as regards type, quantity and time, to the needs of the plants and of the soil, taking into consideration the nutrients and organic matter available in the soil as well as the site and cultivation conditions; the nutrient needs of the plants in consideration of their productivity under the prevailing site and cultivation conditions and to the standards of quality of the produce".

Further details are regulated by a fertilizer decree (Düngeverordnung of January 26, 1996). Aside from restrictions and prohibitive rules on the application of substances, it is intended to achieve and guarantee a selective fertilization that avoids any overprovision of nutrients by obliging farmers to make soil analyses and written records and checks of fertilizer use. From the ecological point of view the fertilization decree is help up as an example for regulations in other fields of agricultural production.

The recycling and waste law (⟶ Waste) can stipulate prohibitive rules and restrictions concerning contaminants for the application of manures and secondary raw material fertilizers.

The German soil protection law (Bundesbodenschutzgesetz, BBodSchG), which is in draft form, is intended to protect the soil from damages. The landowner is forced to practice precautionary soil protection, which naturally applies also to the application of materials such as fertilizers.

5.3.1.3. *Forms of Fertilizers*

(⟶ Fertilizers)

The fertilizers applied can be divided into inorganic and organic fertilizers.

Inorganic fertilizers contain inorganic nutrients or release them after a reaction. Since the nutrients are frequently water-soluble salts or salt mixtures, they are usually available to plants immediately after application or their period of availability can at least be calculated. However, adverse effects can occur when these fertilizers are not properly used; in particular, too high a supply of readily soluble nutrients can lead to increased nutrient loads of the soils and nutrient losses, in addition to reductions in crop yield and quality.

Organic Fertilizers. Two types of organic fertilizers exist, (1) *commercial organic fertilizers*, which are produced by the processing of peat (⟶ Peat – Peat Processing Technologies) or of vegetable and animal materials (⟶ Fertilizers – Organic Fertilizers (Secondary Raw Material Fertilizers)) and are important in the backyard sector at most, and the *organic manures* whose origin is animal (liquid manure, slurry, solid manure) (⟶ Fertilizers – Manure). The nutrients of organic fertilizers are organically combined to different degrees, depending on the type of fertilizer and must the mineralized in the soil in order to be taken up by the plants. Since mineralization processes are highly dependent on temperature and soil moisture, the nutrients are not always available specifically and the amounts taken up by the plants cannot be calculated. The feeding of crops via organic fertilizers therefore makes great demands on the farmer, especially because the nutrient contents of organic fertilizers can vary within wide limits and the precision of application is not optimum.

With the amendment to the German Fertilizer Law of September 27, 1994, *sewage sludge and other wastes* also are for the first time assigned to the fertilizer sector as “secondary raw material fertilizers.”

5.3.1.4. *Effects of Fertilizers in the Soil*

Fertilization pursues several goals. On the one hand, the real task of fertilization — feeding the crop plants with the aim of improving the harvest in quantity and quality — must be carried out; and on the other the soil's fertility must not be threatened. Fertilization can affect various parameters of the soil and therefore the soil's fertility. Strongly influenced are chemical characteristics of the soils (nutrient concentration, soil reaction, pollutants and heavy-metals content), followed by biological parameters (humus content, soil edaphon). Soil-physical parameters are relatively little affected by fertilization.

5.3.1.4.1. Nutrient Contents and Nutrient Losses

(⟶ Fertilizers – Soil Science)

Fertilization should supply the soil with plant nutrients without enriching it with nutrients beyond a tolerable extent. The tolerability in this connection corresponds less to the concentration above which toxicity symptoms appear than to the contents above which increased nutrient discharges occur from the soil to groundwater, surface waters, and the air. If soil pollution by nutrient enrichment can be spoken of at all, it is by possible environmental loads as a result of losses from the soils. In addition, disproportionately high concentrations of certain nutrients in particular impair the composition of the plants via the nutrient uptake and reduce yield and quality.

Nitrogen. More than 90 % of the nitrogen present in soils is combined in the organic matter. Depending on the depth of topsoil and humus content, between 2000 and 10 000 kg nitrogen per hectare are stored under Central European conditions. This nitrogen is mineralized by microbial conversion processes and released as ammonium (NH_4^+); at an average annual mineralization rate of 2 % about 40 –200 kg of nitrogen per hectare and year are supplied. The NH_4^+ formed can be bound by the exchange complex in the soil, but in aerated soils usually undergoes nitrification by bacteria to nitrate (NO_3^-). Nitrate is not adsorbed in the soil, is thus freely mobile, and is the most important nutrient form of N for plants. High nitrate concentrations in the soil solution are advantageous if they are provided specifically in the period of uptake by the plants and can be largely utilized by these plants.

In the absence of uptake by plants or if the nitrate supply exceeds the uptake capacity of the plants, NO_3^- is displaced from the root space as a result of the movement of water in and out of the soil. A surface runoff or discharge via drainage water contributes to the eutrophication of surface waters and the seas; increased contents of nutrients (N in particular) bring about increased algae growth which results in decreasing oxygen contents in the water. A far greater part in public discussion is played by the washing-out of nitrate from the soil and its translocation into the groundwater, which can greatly impair the drinking water quality. Both during the nitrification and especially during the denitrification in the soil nitrous oxide as an intermediate product of these processes can escape and contribute to the greenhouse effect [284].

Before the influence of fertilization on the nitrogen content and nitrogen dynamics in the soil as well as on potential nitrogen losses is described, it has to be pointed out that the agricultural use itself already decisively interfers with the natural nitrogen cycle. Because of the complexity of the effects of individual variables, the influence of fertilization on nitrogen loads in soil will not be exactly quantified in the following.

In long-term nitrogen fertilization the amount of combined nitrogen in the soil is influenced both by the level of fertilization and by the form of fertilizer chosen. Compared with similar, but unfertilized soils, soils exploited agriculturally have higher humus contents with greater depths of topsoil and higher nitrogen contents. The extent of the accumulation of organic matter and therefore also of organically combined nitrogen as a result of long-term fertilization is very strongly influenced by temperature and rainfall [285]. Not only the productivity but particularly the reliability of yield of soils, which is independent of current fertilization, can be improved by raising the N contents and the additional N supply. With the exception of crops that react to higher N supplies from the soil with a decrease especially in processing quality (brewing barley, sugar beet, etc.), the positive aspect of the feeding of crop plants predominates. Moreover, N fertilization positively affects the soil biota and the microbial biomass in the soil [286]. The nitrogen-fixing microorganisms whose activity falls with increasing nitrogen supply are an exception [287].

In addition to the level of N compounds supplied, the type of fertilizer especially influences the amount of nitrogen stored in the soil. Since organic nitrogen fertilizers already contain the nitrogen in the storage form found in the soil, they can raise the N contents in the soil more rapidly and — via higher reproduction rates of the humus in the soil — also more effectively than inorganic nitrogen fertilizers [288]. Long-term fertilization with liquid manure improves the humus and nitrogen contents by about the same order of magnitude as an equivalent dosage of farmyard manure [289]. The chain of action following inorganic fertilization — more plant growth bringing about a greater additional supply of organic matter — also can have a positive influence on the nitrogen concentration in the soil [290], [291]. A combination of farmyard manure and inorganic fertilization can increase the N content more than farmyard manure alone [285]. Hydrolyzable organic N compounds give the most important contribution to the higher total N contents [292].

With increasing additional nitrogen supply from the organic matter or with increased direct N fertilization, there is an increased risk of nitrogen losses from the soil which exceed an unavoidable basic emission [293], [294]. The factor usually responsible for increased nitrate discharges is a discrepancy between the amount and the period of time of the NO_3^- supply in the soil and the amount extracted by the plants during the same period of time. In this connection, the form of the applied nitrogen plays a minor part: thus, even with ecologically cultivated lands, high nitrate translocations are observed under certain conditions [295]. The limit of the N fertilization level above which environmental loads occur depends on many factors (soil, weather, rotation of crops, etc.) and cannot be defined in general. At present the nitrate content in the soil is determined after the harvest of a crop at the start of the translocation period in the autumn and used as a criterion for a balanced NO_3^- supply during the period of uptake by plants [296]. Nitrogen balances also can give clues to a possible risk potential from a N fertilization measure. However, they do not permit direct conclusions on the nitrate discharge [297], [298]. Beyond that, computer simulation models of the nitrogen cycle are being developed that shall reproduce the processes of N dynamics in the soil [299] and thus can provide concrete informations for an N fertilization that accords with requirements and is environmentally acceptable. Even though, the models are not yet suitable for practical use at the present time [300] because of the large number of input parameters, they will become important in future.

The influence of N fertilization on losses in the form of nitrous oxide cannot be estimated at present. All fertilization measures that trigger nitrification and denitrification processes in the soil contribute to nitrous oxide formation in the soil. Even if N_2O is released in any conversion of organic matter (also in the absence of fertilization) [301], it can be assumed that these losses will be greater after N fertilization [302]. Organic and ammonia-containing fertilizers increase N_2O production at a higher extent than nitrate fertilizers [303]; in all, the N_2O emission level probably depends less on the form of fertilizer than on its amount.

Phosphates. Fertilizer phosphates are absorbed in the soil, especially by iron oxides, and thereby fixed. Because of their low mobility, phosphates accumulate mainly in the topsoil. With rising P fertilization the translocation into the subsoil increases, however, losses from the root zone can be observed only under special conditions (peat soils, [304]). Phosphates from organic fertilizers are more mobile in the soil and, compared with phosphates from inorganic fertilizers, can be translocated into deeper soil layers. However, the phosphate contents in groundwaters near the surface is not increased [282], [305]. The removal of phosphates from the surface soil by erosion and drainage water can more likely be of ecological relevance.

Phosphate fertilization raises the P contents in the topsoil, as is shown by comparison with nonfertilized forest sites. If the P concentrations necessary for plant nutrition are not substantially exceeded no harmful effects in the soil from P fertilization are to be expected.

Potassium. Fertilization with potassium can raise the potassium contents, depending on the buffering capacity of the soil. A disproportionately high K supply can hinder the magnesium uptake by plants and so induce a Mg deficiency [306]. In isolated cases, too high potassium concentrations which, however, occur in practice only as the result of a long-term excessive potash fertilization, can impair the quality of crop products. Avoidable losses from the soil as a result of fertilization measures can occur on light soils [294], [307], but no ecological relevance is known.

5.3.1.4.2. Soil Reaction

Agricultural production is possible only on soils with a soil reaction that is optimum for crop plants. This optimum reaction depends on the kind of plant, the nutrient contents, the kind of soil, and the soil struture. From the plant nutrition standpoint, the optimum pH values are considered to be 6 – 7. In this range most microorganisms [286] and the soil edaphon also show their highest activity. As a result of the natural acidification of the soil by translocation of alkali metal and alkaline-earth metal ions from the soil, which is further reinforced by agricultural production, it is usually necessary to raise the pH value.

Fertilization measures can decisively influence the extent of soil acidification. Ammonium-containing fertilizers, which are nitrified in the soil and in the course of this release H^+, have a physiologically acidifying effect. Since inorganic N fertilization is carried out worldwide mainly using NH_4^+ containing fertilizer, N fertilization contributes considerably to the lowering of the pH value and involves an increased lime requirement. Phosphate-containing fertilizers that are obtained by solubilizing apatites or are combined with Ca in the course of production can promote the soil reaction. Organic manures show no short-term effect on the soil reaction but in the long term can lead to an increase of the pH value by replacement of cations [308].

Through liming, the natural soil acidification and the lowering of the pH value as a result of fertilization measures and acidic inputs from the air can be compensated. This is true not only for agricultural but also, e.g., for forestry lands.

5.3.1.4.3. Humus Content

Humus influences the chemical, physical, and biological properties of soils and is thus an important factor in soil fertility. The humus content is essentially determined by quantities typical of the site, such as nature of soil and climate as well as the conditions for conversion of the organic matter and the possibilities of formation of durable humus materials. Within the limits set hereby, the fertilization can influence the humus content.

Obviously, the humus content of soils can best be influenced by organic fertilizers. Long-term application of solid or liquid manure improves the humus content for a long time afterward. Similar effects are produced by compost and sewage sludge. The humification rates in this connection decrease with increasing supply of organic matter and increasing humus content of the soil [318]. Inorganic fertilization can improve the humus content to a limited extent by way of an increase in the vegetation cover and the resulting crop residues (straw, foliage, green manure) or the humus content can at least be maintained with regular working-in [310]. Only in crop rotations with high proportions of root crops, crop and root residues even in increased amounts cannot prevent a decrease of the humus content and fertilization in organic form is necessary [311].

Very close relations exist between the organic matter content of the soil and its nitrogen pool and nitrogen supply capacity. It is today very questionable from the ecological standpoint to improve the humus content typical of the site by intensive fertilization measures, because with this the risk of N losses detrimental to the environment increases.

5.3.1.4.4. Heavy Metals and Organic Pollutants

Even though heavy metals occur naturally in all soils, a possible accumulation in the soil as a result of fertilization measures must be avoided. The ecological relevance of an accumulation in that connection consists not so much in increased emissions but rather in an increased uptake of heavy metals by plants with the risk of an impact on the health of humans and animals. Similar effects are to be exptected from an application of toxic organic pollutants.

Inorganic fertilizers and farm-produced manures usually contain no organic pollutants and only occasionally small amounts of heavy metals that are not hazardous to the soil. Phosphate fertilizers, which are made from crude phosphates of organogenic origin, can contain considerable amounts of cadmium. By avoiding the use of highly contaminated crude phosphates, the Cd content of P fertilizers has been reduced and currently is usually not more than 40 g/t P_2O_5; hence only an extremely small Cd enrichment occurs in the soil [312]. In the EU countries limit values have been drawn up for further reducing the undesirable Cd intake. The level of Cd intake can in addition be influenced by the form of fertilizer chosen [313].

Farm-produced manures also can contain heavy metals; high Cu and Zn contents in pig manure originating from the pig feed considerably exceed uptake by plants and these metals can accumulate in the soil over the long term. The risk of a possible load has been reduced as a result of the restriction of fertilization by liquid manure (see Section Legal Framework of Fertilization) and to the restriction of copper feed supplements by the German law on feed materials (Futtermittelgesetz).

With the parity of legal treatment between sewage sludge and farm-produced manures, a possible load of soils by “fertilization” with sewage sludge could occur in the future. The present stage of the discussion is given below:

1. If disposal areas are limited, there is a high sociopolitical pressure to use sewage sludge alternatively on agricultural lands
2. From the scientific standpoint, the pollutant tolerance levels of the soil and the permissible pollutant contents are controversal subjects of discussion and in some cases called in question
3. In agricultural practice the reservation against the use of sewage sludge prevail, despite considerable financial incentives

Sewage sludges have a relatively small fertilizing and soil-improving effect and are not necessary as fertilizers from the plant nutrition standpoint. Possible soil loads from the application of sewage sludge have to be justified not by agriculture but by society and the political world in their desire for waste disposal using agricultural areas.

5.3.2. ***Pesticides (*** → Crop Protection; → Acaricides; → Fungicides, Agricultural; → Insect Control; → Molluscicides; → Nematicides; → Rodenticides; → Weed Control***)***

5.3.2.1. *Introduction*

Pesticides are in general formulations of active substances and formulation aids. *Active substances* are chemically defined substances or mixtures of substances and are the actual carriers of the plant-protecting action. The *formulation aids* (e.g., solvents and extenders, deposit builders, emulsifiers, wetting agents, stabilizers, and warning dyes) provide the mixtures with the physical properties which make them suitable for application as sprays, dusting agent, etc. in solid, liquid, or gaseous form. Pesticides arrive, either directly or via the crop plants, onto and into the soil or in groundwater and surface water.

Pesticides are used in agriculture, forestry, industry, and in urban areas. They are frequently used for medical and military purposes. Agriculture forms the largest sales outlet for pesticides. Thousands of tonnes are applied worldwide each year, including 110 000 t in the Federal Republic of Germany alone in 1981 [314-316], the use of herbicides and insecticides being predominant internationally. Various pesticides and their chemical structures are given below. They have been selected mainly from chemical considerations and less from their economic importance or biological action (I = insecticide, H = herbicide, F = fungicide, A = acaricide).

Alicyclic insecticides

Linuron

36

The utilization and the toxicity of pesticides is decisively influenced by their behavior in the environment. They can be adsorbed/desorbed, vaporized, leached out, biodegraded and changed photochemically [314], [316], [317]. These processes are clearly influenced by abiotic and biotic factors. Important factors are physicochemical properties of the pesticides such as solubility, volatility, mobility, and degradability [318-320], but also the soil characteristics and the boundary conditions.

Mobility means the translocation of the pesticides in the soil. The mobility is strongly dependent on the water solubility and the sorbability of the pesticides. The water solubility of the individual pesticides varies within wide limits. While triazoles, phenoxy fatty acids, and the benzoic acids have a high water solubility of more than 500 mg/L, chlorinated hydrocarbons such as DDT, aldrin (**2**), and heptachlor (**4**) are only slightly soluble (<1 mg/L, Table 23). The mobility of pesticides is determined under laboratory conditions using percolation tests with soil columns. The organic matter and the clay content of a soil and the pH value have to be taken into account as important factors in this connection. The herbicides 2,4-(dichlorophenoxy)acetic acid [2,4-D, (**29**)] and 2,4,5-(trichlorophenoxy)-acetic acid [2,4,5-T, (**31**)], for example, percolate as rapidly in a low-humus subsoil (pH = 6.6, 0.26 % C_{org}, 19 % clay) as tritium-labeled water, because at pH values above 4 they are not bound to clay ([314]). In the cases of monolinuron (**34**) and chloridazon, a translocation in humus-containing soil (pH = 6.4, 3.2 % C_{org}, 8 % clay) could not be detected. Generally, the adsorption on soils with a very low content of organic matter is small. With high content of organic matter, an increase of adsorption is usually found. It can be assumed that both very low and very high contents of soil organic matter retard the degradation of active substances and reduce their effect. In the case of numerous active substances, 60 – 95 % of the substances used can be immobilized by adsorption.

Table 23. Properties and mode of action of crop-protection agents in soil at doses used in practice and favorable conditions of degradation (11 – 16 °C, loose, loamy arable soils, pH 5.5 – 6.5, 2 – 4 % humus, [314]) [a]

Common name (action) [b]	Chemical name	Prohibited, permitted (FRG) [c]	Solubility	Volatility	Bonding by			Degradation		Mobility	Formula

[c] Since 1988 prohibited, + permitted, ( ) prohibited in water protection zones since September 1, 1988 (Pflanzenschutzanwendungsverordnung).

Transformation. Pesticides can be biologically transformed (cometabolized) in the soil under aerobic or anaerobic conditions and/or degraded to CO_2 and H_2O (mineralized). In the course of the degradation process, metabolites, which can be harmless or toxic, can be formed.

In the presence of microorganisms pesticides undergo oxidations, hydrolyses, and aerobic and anaerobic ring cleavage [318], [320]. The stability of the pesticides in the soil is described by their half-life ($t_{1/2}$). The half-lifes are regarded as ecologically relevant band-widths of stability. If deviations from an average band-width occur, this is in most cases due to soil properties or soil/environment conditions that lead to particularly low or particularly high stability of active substances [316]. Degradation rates usually mean the disappearance of the pesticides within a certain period of time. The majority of the test systems previously proposed and used for pesticide degradation in the soil assume that the active substances are retained in the Ap horizon and are also degraded there. However, because of the detection of certain pesticides in the groundwater [321], [322] the reactions and effects in the subsoil were investigated to an increased extent [323].

The *biodegradability* of the active substances is influenced by biological factors such as the quantity of the microbial biomass, the physiological state (activities), and adaptability of the microorganisms.

Factors such as temperature, salinity, water content, oxygen availability and the supply of organic substances determine the composition of the microbial populations at the site and

have therefore to be considered during the application of the pesticides.

On the soil surface, pesticides are *photochemically degraded* and *chemically converted*. Pentachlorophenol and DDT can be degraded photochemically, e.g., in presence of UV radiation to CO_2 and hydrochloric acid. Chemical conversions of the pesticides also occur by hydrolysis, oxidation, and isomerization.

Table 23 shows that the pesticides differ greatly in their biological and chemical degradability. While the phenoxy fatty acids can be degraded in arable soils, mainly in their topsoil, in about 18 weeks, pentachlorobenzene and the majority of the chlorinated hydrocarbons remain detectable for many years.

Behavior in the Environment. The applied amount, the formulation, and the type of application are very important for the action and the environmental behavior of pesticides. The interplay of the various factors finally determines the actual behavior of the pesticides in the environment.

Composition and properties of pesticides and their behavior in soils at doses used in practice and favorable degradation conditions are listed in Table 23 [314].

Legal Aspects, Test Systems. The use of pesticides causes a contamination of the soils; the magnitude of the enrichment depends on the persistence of an active substance, the amount and frequency of application, and also on the sorption, degradation, and translocation conditions of the soil [317], [319]. The formation of pesticide residues in agricultural soils as well as the contamination of groundwater and surface water cannot be excluded. According to the German law on crop protection (Pflanzenschutzgesetz), pesticides, if applied properly, must have no impact on humans, animals, or groundwater and not affect the natural economy in a way that does not comply with the present state of scientific knowledge. In order to guarantee these requirements, pesticides are subjected before use to extensive studies, so that sufficient information is available on their behavior (physicochemical properties, adsorption/desorption, degradability, etc.) and possible side-effects on plants, selected animals, and microorganisms under standardized laboratory conditions. Test systems for determining the behavior of pesticides, such as the degradability or the percolation behavior in soil columns have been introduced in the industrialized countries and by international organization (OECD, EU, WHO, FAO). Test systems such as those for acute and chronic toxicity, mutagenicity, carcinogenicity, and bioaccumulation are used for estimating the risk potential [324-330]. The information gained is only to a limited extent applicable to the ecosystem. According to experience with aquatic organisms, the informative value of tests can certainly be increased by compilation of test batteries, but the uncertainties remain considerable.

In the soil area the action of the pesticides on the whole microbial population can be estimated. With the exception of the oxidation of ammonia to nitrite (nitrification) the microbial indicators used hitherto, such as respiration, enzyme activities, or bacterial counts, have not been very sensitive. This was actually to be expected, because the ecological relevance of the result of a measurement generally increases dramatically with multi-species test system, usually at the expense of sensitivity [324]. Investigations of the action of pesticides under field conditions are certainly desirable. At present this seems difficult for logistical and financial reasons and because of the low reproducibility of the results.

Almost all known tests investigate the action of environmental chemicals under aerobic conditions. Anaerobic test systems are hardly available [325], [331]. It is to be expected, though, that aerobic degradation will differ greatly from anaerobic degradation, with regard both to the composition of the microbial populations and to degradation pathways. An action of the pesticides differing according to O_2 availability is therefore to be expected. ALEF et al. [332] have developed the arginine mineralization as a simple and reproducible method for estimating the action of environmental chemicals on anaerobic microbial populations. Both the NOEL and the EC_{50} values can be determined from the dose – response relationship (Fig. 19; the greatest inhibition of the arginine mineralization by the environmental chemicals was usually found on the third day of incubation). The new method can be used for determining the acute and chronic effects of environmental chemicals [332].

Figure 19. Action of 2,4,5-T on the anaerobic arginine mineralization; data in % of the control values [332]

Spheres = 2 days; triangles = 3 days; squares = 4 days

To obtain registration for a pesticide, generally studies carried out under defined “worst-case” conditions must be submitted investigating the effect on soil microorganisms and on selected organisms. The results obtained give information on the behavior of pesticides in the environment; they should be reasonably comprehensive so that the authorities can make a decision taking into account the intended use. The objective of the investigations can never be a complete picture of the behavior of the pesticides in all environmental compartments.

5.3.2.2. *Side-Effects*

Pesticides can interfere with various processes in the cell. Their mechanisms of action differ [333]. While photosynthesis is the main point of attack for herbicides, fungicides attack nuclear division, nucleic acid and protein synthesis, respiration, biogenetic pathways, and the membrane function. Insecticides influence respiration and the membrane structure.

To be able to use pesticides profitably, active substances are required whose selective action on crop plants is as different as possible from that on target organisms. A very high specificity of action, though, is not always achievable. Herbicides, for example, can influence respiration and biogenetic pathways aside from photosynthesis, and also inhibit germination. Undesirable effects on soil organisms, plants, animals, and humans can therefore be expected. Pesticides can reach humans via the food chain or drinking water.

Side-Effects on Soil Organisms. The action of pesticides on soil organisms is to be regarded as negative if the soil biota is so extensively disturbed that essential functions of the ecosystem such as decomposition and humification, aggregation, nutrient immobilization and mobilization, loosening, and bioturbation are lastingly impaired. In this connection, negative effects can be called “critical” that last for more than one month [316], [334]. From the standpoint of species preservation, action of pesticides should preferably also not lead to any complete change of species or at least guarantee a rapid recolonization after the specific use of soil is finished. The potential regenerability of the soil biota has in any case to be preserved.

The effects of herbicides, fungicides, and insecticides are not completely specific. Their action depends on the concentration used, on the mode of application, and on the properties of the site. Fungicides such as benomyl and thiabendazole, for example, can have a negative effect on earthworms. Other pesticides can influence bacteria and stimulate ammonification.

Herbicides such as paraquat, linuron, and 2,4-D can stimulate bacterial activities (e.g., respiration), but on the other hand injure algae [335-337]. Insecticides can in some cases also act as nematocides and then be used as such. Carbamates and phosphate esters are in some cases toxic to earthworms and their activity even at a normal dose [335].

Different site conditions not only modify the expected impact of pesticides but can also lead to different side-effects, a topic which has been little studied up to now. It is impossible to consider all environmental factors in the laboratory test; notwithstanding that, basic information on the possible ecotoxicological action of pesticides is indispensable in practice.

Various groups have proposed uniform procedures or tests of estimating the action of pesticides on soil microorganisms (respiration, substrate-induced respiration, nitrification, N mineralization, dehydrogenase activity, [334]). A series of data is available in the literature, on the effect of pesticides on the composition of microbial populations (bacterial counts, fungal counts, or plate counts). This information should be regarded with caution, especially because no uniform procedure is given and comparability of the data is therefore scarcely possible. Furthermore, reliable information on the action of pesticides on the interactions between the various organisms in the soil is scarcely obtainable. There is a great need for research in this field.

Uptake, Accumulation, and Side-Effect on Plants. In principle, the uptake and accumulation of pesticides can occur in all parts of plants. This depends on the plant species, on the physicochemical properties of the substances and on the site (pH value, content of organic substances in the soil, soil structure).

In *soil application*, pesticides are absorbed with the soil water by the plant roots and transported in the xylem. With high vapor pressure, the active substances can also reach the roots in the soil airspace.

In *leaf application*, the pesticides can penetrate into the leaf by diffusion. The uptake is considerably easier for lipophilic than for hydrophilic substances. Both in soil and in leaf application the active substances can accumulate in the plant leaf. However, pesticides can also remain at the site of application, and not be transported in plants. Aside from the positive effects of pesticides, negative effects can also occur. The side-effects can extend as far as to serious damage [338]. Under extreme weather conditions, damage, e.g., to crop plants cannot be ruled out. After the use of urea derivatives, for example, an increased attack by fungi has occasionally been observed in grain cultivation. The selectivity of the active substances is of great importance and is therefore tested during the registration process.

A consequence of the use of pesticides in agriculture is that occasional residues in foods cannot be prevented. In order to be able to estimate the risk potential, both the acute and the chronic action on animals (e.g., rats, guinea-pigs) are tested during the registration process. In these studies, the NOEL value (⟶ Toxicology – Toxicological Studies: General Aspects) for the experimental animal is determined. In application to humans this maximum inactive dose is still for safety's sake reduced by a factor of at least 100. From this, there is obtained the highest still acceptable daily dose in milligrams per kilogram food (ADI; ⟶ Foods, 3. Food Additives – Safety Aspects; ⟶ Insect Control – Toxicology of Insecticide Residues). To prevent that the maximum quantity regulation is exceeded when using pesticides, the concept of “waiting time” is introduced. This means how many days before the harvest of the crop, at the latest, a pesticide may be used to make sure that the maximum amount is not exceeded. As a result of the maximum quantity regulation, the marketing of foods with excessive pesticide residues is forbidden [339]. The strict conditions cannot, however, completely prevent human foods from containing pesticide residues [340].

Contamination of Groundwater and Surface Waters. Because of their mobility, pesticides can be translocated after their application into the groundwater and surface water. Despite high dilution in the surface water, however, remobilization, can occur. The pollution of surface water by polluted groundwater depends on the length and bonding strength of the filter section, the groundwater flow rate, and the degradation rate of the pesticides in the groundwater. With long-term and intensive use of mobile active substances on the soil, pollution of the groundwater must be reckoned with.

In order to protect water bodies from contamination by pesticides, national and international regulations have come into force in which the maximum permitted concentrations have been stipulated. The EC drinking water regulations, for example, provide that drinking water may contain no more than 0.5 µg/L of pesticides in total and 0.1 µg/L of a single active substance.

5.4. Effects of Abandoned Waste Disposal Sites

5.4.1. ***Introduction***

The genesis of contaminated sites is different from site to site. A distinction can be made, however, between those sites in which the chemical nature, quantity, number and distribution of the contaminants are largely production-specific and those in which they are waste- and deposition-specific.

The first group includes contaminated plant sites (*contaminated land*). Aside from different localities and extents, these sites also differ in the arrangements of manufacturing plants, handling facilities for water-endangering substances, intermediate storage facilities, waste deposits, etc., depending on the type of plant (gasworks, oil refinery, a factory for manufacturing explosives, weapons, plant-protection agents, dyes, etc.). Old sites are contaminated from specific manufacturing operations or production residues. At present no statistically supported results on the extent of this contamination exist. In addition, usually no data are available on the persistence and mobility of specific contaminants in soil and groundwater and on their possible ecotoxicity or human toxicity.

The situation is usually different in the case of abandoned waste disposals (*abandoned sites*). By contrast with the contaminated land, from which dangers often arise only from changes in ground use (e.g., excavation of foundation pits) or by direct contact with "easily accessable" hazardous substances (for example by children at play), dangers originating from old deposits can be attributed almost entirely to their emissions. Especially important are the leachates, loaded with considerable quantities of pollutants that reach the soil and subsequently the groundwater and can then endanger its use as drinking water. In Germany alone account must be taken of more than 100 000 old deposits. This kind of contamination of soil and groundwater therefore represents a problem also with regard to the area concerned, which is steadily increasing because the pollutant plumes continue to expand in the groundwater. This section describes the qualitative and quantitative effects of leachate emissions from abandoned waste disposals on groundwater.

5.4.2. *Material Contents in Groundwater Affected by Abandoned Waste Disposal Sites*

Inorganic Substances. The natural substance contents of groundwater are changed considerably by the leachates of abandoned sites [341]. Table 24 assembles the mean, median, and other percentile values calculated for contaminated groundwaters from unconsolidated rocks, together with the maximum values of the various inorganic parameters.

Table 24. Inorganic constituents of groundwaters contaminated by abandoned waste disposal sites and their statistical parameters

Parameters	DL [1]	Number of measured values [2], *n*	*n* >DL	DF[3], %	Mean A[4]	Mean B[5]	Median 50 % percentile	75 % percentile	Maximum

[1] DL = Detection limit.
[2] In some cases the mean values of one well are used, therefore *n* is the number of measured wells.
[3] DF = Analytical detection frequency (percentage from *n* > DL to n_{total}).
[4] Arithmetic mean of all measured values including maximum value.
[5] Arithmetic mean rejecting maximum value.

Organic Substances. As regards the number of substances the possible contamination of groundwater in the outflow from abandoned sites by organic compounds is far greater than that by inorganic compounds. About 1200 organic groundwater contaminants have up to now been detected by extensive GC – MS analytical studies in Germany and the United States [342] in the outflow from abandoned disposal sites. Only a relatively small number of these contaminants, however, are detected fairly frequently and at the same time have concentrations distinctly above 1 µg/L (United States) or above 0.1 µg/L (West Germany), respectively. The majority of the identified organic contaminants (>1000) have a detection frequency (DF, see Section Emission Detection Frequency) of less than 0.1 %; i.e., in 1000 contaminated groundwater samples polluted by abandoned waste deposits they are detected on average less than once.

A bias for substances or classes of substances detected in the contaminated groundwater due to the analytical method used can be almost ruled out because the sample preparation (substances extractable under acid or basic/neutral conditions, highly volatile substances, and pesticides) and the analytical method (essentially GC – MS) were aimed at the detection of the largest number of groundwater contaminants possible [343], [344].

Table 25 lists, in the order of decreasing *detection frequency*, the important organic groundwater contaminants determined in Germany (former Western Germany) with various statistical parameters of their concentrations. Of the 19 contaminants with detection frequencies ≥10 %, 12 (63 %) are volatile halogenated hydrocarbons. Of these, 5 are alkane derivatives, 4 are alkene derivatives, and 3 are chlorosubstituted benzenes. Among the 7 halogen-free contaminants, benzene and its alkyl derivatives (4 compounds) are most important; in addition 2 phenols and naphthalene have detection frequencies ≥10 %.

[1] Detection limit.
[2] In some cases mean values of one well are used, therefore *n* is the number of measured wells.
[3] Analytical detection frequency (percentage from *n* > DL to n_{total}).

Highly volatile halogenated hydrocarbons also show the highest *mean concentrations* in groundwaters, both when evaluated from the concentrations themselves and when evaluated from the logarithms of the concentrations. Dichloromethane (38 mg/L and 871 µg/L, respectively), *cis*-1,2-dichloroethylene (22 mg/L and 234 µg/L, respectively), vinyl chloride (ca. 1.7 mg/L and 85 µg/L, respectively) and trichloroethylene (ca. 1 mg/L and 11.5 µg/L, respectively) should be mentioned in the first place, so confirming quantitatively the dominance of these compounds as groundwater contaminants from abandoned waste disposal sites [345].

5.4.3. *Contamination Criteria and their Quantification*

The influence of leachates from abandoned sites on the groundwater can be characterized and quantified by comparing for relevant substances the statistical parameters of data records of contaminated and noncontaminated groundwaters calculated from the concentrations determined. In the case of inorganic substances, the geogenic fraction must be taken into account and in the case of a few organic substances the ubiquitous contamination by these compounds.

5.4.3.1. *Contamination Factor*

The contamination factor (*CF*) of a substance represents the ratio of the observed concentration in the contaminated area to the concentration in the uncontaminated area of a site [346]. The contamination factor indicates how many times the concentration of a substance in the groundwater at the contaminated area is increased compared with that in the unaffected area. It is therefore a measure of the intensity of the effect of a substance on groundwater. It is furthermore also an indirect measure of the mobility and persistence of a contaminant on the emission path from the waste site into the groundwater, because only substances that are highly water soluble, have a low sorbability on C_{org} and clay minerals (i.e., a low geoaccumulability), and that are not or not rapidly degradable can ocur in significantly enhanced concentrations in groundwaters.

As a measure of the strength of influence of the individual *inorganic parameters*, the ratio is formed of the mean, rejecting the maximum value, from the data record of the contaminated groundwater (see Table 24) to the mean from the data record of groundwaters that are unpolluted or affected as little as possible (see [341]). In principle a contamination factor can be calculated for other statistical parameters also (median, percentile values, maximum value). A subscript is used (as in CF_{mean} in this case) for differentiating the contamination factors. For all inorganic parameters studied, with the exceptions of selenium and nitrate, the contamination factors CF_{mean} are >2 (Table 26). Values >20 are reached by ammonium (CF_{mean} 64.7), arsenic (CF_{mean} 37.8), chromium (CF_{mean} 36.6), and boron (CF_{mean} 23.9). Values >10 are found for phosphate (CF_{mean} 12.9), aluminum (CF_{mean} 11.9), cadmium (CF_{mean} 11.5), and potassium (CF_{mean} 11.3). This verifies the strongly increased concentration of these substances in groundwaters as compared with their natural concentrations.

Table 26. Inorganic groundwater contaminants from abandoned waste disposal sites listed in the order of decreasing contamination factors

Substance	Mean*, contaminated**	Mean, uncontaminated [341]	Contamination factor (CF_{mean})
Ammonium, mg/L	11.0	0.17	64.7
Nitrite, mg/L	0.49	<0.01	>49.0
Arsenic, µg/L	45.4	1.2	37.8
Chromium, µg/L	21.2	0.58	36.6
Boron, µg/L	832.	34.8	23.9
Phosphate, mg/L	1.8	0.14	12.9
Aluminum, µg/L	596.	50.	11.9
Cadmium, µg/L	1.5	0.13	11.5
Potassium, mg/L	32.9	2.9	11.3
Manganese, mg/L	1.5	0.18	8.3
Nickel, µg/L	22.9	2.8	8.2
Sodium, mg/L	128.	17.5	7.3
Chloride, mg/L	202.	33.4	6.0
Iron, mg/L	9.6	2.0	4.8
Lead, µg/L	6.3	1.4	4.5
Zinc, µg/L	410.	117.	3.5
Copper, µg/L	24.5	7.0	3.5
Sulfate, mg/L	194.	59.0	3.3

Magnesium, mg/L	38.1	14.3	2.7
Strontium, µg/L	580.	240.	2.4
Hydrogencarbonate, mg/L	519.	238.	2.2
Calcium, mg/L	175.	83.2	2.1
Nitrate, mg/L	25.6	13.3	1.9
Selenium, µg/L	0.10	0.55	0.2
Fluoride, mg/L	<0.5	<0.1	
Mercury, µg/L	<0.2	<0.1	

* Arithmetic mean, rejecting maximum value.

5.4.3.2. *Emission Detection Frequency*

The emission detection frequency of a substance is by definition the percentage of detections of a substance that has entered the groundwater with the leachate from the abandoned site [for example, if the boron contents of 259 contaminated groundwater samples (different wells) is determined and the concentration in 222 samples is higher than the background, the emission detection frequency is 85.7 %]. It is important in this connection whether an emitted substance (contaminant) can occur naturally in the groundwater or not. Naturally occurring are almost all inorganic contaminants, but not the purely anthropogenic organic substances. To recognize an increase of contents of the natural inorganic constituents of water, their geogenic content must be known.

In the case of the anthropogenic organic contaminants, the natural geogenic “background” concentration is zero; i.e., analytical detection frequency and emission detection frequency are usually identical. In the case of the detection frequency, it is not important — as in the case of the contamination factor — how large the increase is but only that the value is increased.

Inorganic Substances. In the case of inorganic substances, the arithmetic mean value from the data record of the “least affected” groundwaters from unconsolidated rock aquifers is by definition the concentration for the average geogenic background [341]. The number of measured values above this geogenic background value is determined from the data record of the groundwaters affected by abandoned waste disposal sites and the percentage detection frequency calculated. If the background value is below the detection limit, the corresponding detection limit is used instead (fluoride, nitrite, mercury). The results are listed in Table 27. Hydrogencarbonate shows the highest emission detection frequency (85.8 %), followed by boron (85.7 %), sodium (83.4 %), chloride (79.2 %), and magnesium (76.0 %). A lower detection frequency is found for lead (38.3 %), nitrite (35.4 %), aluminum (33.0 %), selenium (22.3 %), cadmium (14.9 %), and mercury (14.7 %).

Table 27. Inorganic groundwater contaminants from abandoned waste disposal sites listed in the order of decreasing detection frequencies

Substance	“Background” (mean unaffected [341])		Number of samples affected*	Number of samples with value > “background”	Detection frequency, %**
Hydrogen-carbonate	238.	mg/L	233	200	85.8
Boron	34.8	µg/L	259	222	85.7
Sodium	17.5	mg/L	338	282	83.4
Chloride	33.4	mg/L	360	285	79.2
Magnesium	14.3	mg/L	321	244	76.0
Calcium	83.2	mg/L	318	237	74.5
Potassium	2.9	mg/L	217	161	74.2
Strontium	240.	µg/L	205	152	74.1
Sulfate	59.	mg/L	352	227	64.5
Nickel	2.8	µg/L	249	160	64.3
Manganese	0.18	mg/L	329	206	62.6
Arsenic	1.2	µg/L	253	155	61.3
Chromium	0.58	µg/L	279	157	56.3
Ammonium	0.17	mg/L	276	148	53.6
Fluoride	<0.1	mg/L	97	51	52.6
Copper	7.0	µg/L	275	144	52.4
Nitrate	13.3	mg/L	347	176	50.7
Phosphate	0.14	mg/L	207	86	41.5
Zinc	117.	µg/L	328	135	41.2
Iron	2.0	mg/L	335	136	40.6
Lead	1.4	µg/L	334	128	38.3
Nitrite	<0.01	mg/L	285	101	35.4
Aluminum	50.	µg/L	168	57	33.9
Selenium	0.55	µg/L	112	25	22.3
Cadmium	0.13	µg/L	335	50	14.9
Mercury	<0.1	µg/L	232	34	14.7

* see Table 24.
** Emission detection frequency.

Comparison of the detection frequencies (Table 27) with the contamination factors (Table 26) shows that a high contamination factor does not necessarily also imply a high detection frequency. Thus aluminum and cadmium have relatively high contamination factors of 11.9 and 11.5, respectively, but comparatively small detection frequencies (33.9 % and 14.9 %, respectively). The reverse situation also occurs (e.g., HCO_3^-, Mg). For inorganic substances high contamination factors in combination with high detection frequencies can be regarded as typical of emissions of abandoned sites into the groundwater. Contamination factors >10 and detection frequencies >50 % are found for arsenic (37.8, 61.3 %), ammonium (64.7, 53.6 %), boron (23.9, 85.7 %), potassium (11.3, 74.2 %), and chromium (36.6, 56.3 %).

Organic Substances. For some organic substances the analytical detection limit is so low that even ubiquitous loadings not attributable to old deposit emissions are recorded. Thus the analytical detection limit for trichloroethylene, tetrachloroethylene and trichloromethane is 0.1 µg/L, whereas the ubiquitous loadings are in the order of up to 0.4 µg/L [345]. Thus, an analytical detection of these substances in the concentration range of the ubiquitous loading cannot be interpreted as the detection of emission from an abandoned site.

For determining the emission detection frequency, the so-called “relevance limit” was created. This is the concentration above which a detection of an organic substance can be attributed with considerable certainty to the emission from an old deposit. In nearly all cases the relevance limit corresponds to the detection limit: only for a few volatile chlorinated hydrocarbons was the relevance limit set at 1 µg/L.

Since in the case of tetrachloroethylene, for example, of 195 measured values above the analytical detection limit (0.1 µg/L), 67 measured values (24.2 %) fall below the relevance limit of 1 µg/L, the emission detection frequency is only 46.2 % (Table 28), compared with the analytical detection frequency of 70.4 % (Table 25).

Table 28. Organic groundwater contaminants from abandoned waste disposal sites listed in the order of decreasing emission detection frequencies

Substance	Number of analyses	Relevance limit, µg/L	Number of measured values > relevance limit	Detection frequency, %
Tetrachloroethylene	277	1.0	128	46.21

Hexachlorobenzene	93	0.1	0	0.00

Table 28 shows, in the order of decreasing emission detection frequencies, the organic substances that have been detected in groundwaters affected by old deposits. Those of prime importance are tetrachloroethylene (DF 46.21 %) and trichloroethylene (DF 40.79 %). Altogether only 7 substances have a detection frequency >20 % and 19 substances a detection frequency >10 %. “Only” 49 substances have a detection frequency of >1 %.

5.4.3.3. *Mean Emission Concentration*

A suitable measure of the quantitative influence of a substance is its mean emission concentration. This is the difference between the mean concentration from affected groundwaters and the mean concentration from unaffected groundwaters of a given origin. In the case of organic substances, the small ubiquitous concentration has a negligible influence on the difference, so that here the mean emission concentration is equal to the mean concentration in the affected groundwaters.

Inorganic Substances. The mean emission concentrations of inorganic substances from abandoned sites are listed in Table 29. For better comparison, all concentrations are listed in the unit µg/L and sequenced in the order of decreasing mean emission concentration. Hydrogencarbonate has the highest mean emission concentration (281 mg/L), followed by chloride (169 mg/L), sulfate (135 mg/L), sodium (111 mg/L), and calcium (92 mg/L). In the old deposit (which functions as a “bioreactor”) CO_2 is formed in significant amounts and converted to HCO_3^-. Thus, hydrogencarbonate must be a principal emitted species, just like Na^+ and Cl^-, which are emitted together (both originating from NaCl). Since construction waste rubble makes up a considerable part of the volume of waste, SO_4^{2-} and Ca^{2+} are also among the substances that are emitted most frequently and in high quantities from abandoned waste disposal sites.

Table 29. Inorganic groundwater contaminants from abandoned waste disposal sites listed in the order of decreasing mean emission concentrations

Substance	Mean[+] affected, µg/L	Mean unaffected [341], µg/L	Mean emission concentration, µg/L
Hydrogen-carbonate	519 000	238 000	281 000
Chloride	202 000	33 400	168 600
Sulfate	194 000	59 000	135 000
Sodium	128 000	17 500	110 500
Calcium	175 000	83 200	91 800
Potassium	32 900	2 900	30 000
Magnesium	38 100	14 300	23 800
Nitrate	25 600	13 300	12 300
Ammonium	11 000	170	10 830
Iron	9 600	2 000	7 600
Phosphate	1 800	140	1 660

Manganese	1500	180	1 320
Boron	832	34.8	797
Aluminum	596	50.0	546
Nitrite	490	<10.	480
Strontium	580	240	340
Zinc	410	117	293

Copper	24.5	7.0	17.5
Chromium	21.2	0.58	20.6
Nickel	22.9	2.8	20.1
Lead	6.3	1.4	4.9
Cadmium	1.5	0.13	1.4
Selenium	0.10	0.55	0.
Fluoride	<500.	<100	
Mercury	<0.2	<0.1	

* Mean rejecting maximum value (cf. Table 24).

Organic Substances. To calculate the mean emission concentration of organic substances, the logarithms of the individual concentrations are first taken, because a few measured values are so high that the arithmetic mean values of concentrations before taking their logarithms are meaningless and make comparison impossible. Since logarithms cannot be taken of the concentrations below the detection limit (exact concentrations cannot be determined, but the substance is present in small amounts), only the measured values above the detection limit are included in the mean emission concentration of the organic substances. This procedure is reasonable also because the detection frequencies of most organic substances are very small (see Table 28), which means that a high proportion of measured values are below the detection limit. If these measured values were to be included in the calculation, most mean concentrations would fall below the detection limit.

Table 30 assembles the organic substances in the order of decreasing mean emission concentrations. The list is headed by dichloromethane and a number of other chlorinated and highly volatile compounds, a fact which again confirms the predominance of this group of organic substances in emissions from abandoned sites.

Table 30. Organic groundwater contaminants from abandoned waste disposal sites listed in the order of decreasing mean emission concentrations

Substance	Number of analyses	Number of measured values > relevance limit	Mean of log. concentrations*	Mean emission concentrations, µg/L
Dichloromethane	114	17	2.94	870.96

6. Measurement and Evaluation of Soil Pollution

Gerhard Knoop, Gerd Crössmann, Thomas Eikmann

6.1. Sampling and Investigation of Soil Pollutants

6.1.1. *Introduction*

Sampling and investigation of samples are integral parts of procedures for the hazard and risk assessment of soil pollution. Soil pollution here means the presence and usually uneven spatial distribution (both horizontally and vertically) of certain substances in soil. These substances either do not occur naturally in these soils or their natural inventory has been enriched to an undesirably high degree by inputs via various exposure paths. The first substance group includes high- and low-volatility halogenated hydrocarbons, aromatic and polycyclic aromatic hydrocarbons, petroleum hydrocarbons, but also organically bound residues of pesticides. Nonessential heavy metals such as lead, cadmium, mercury, and thallium are to be assigned to the second group. Procedures for the detection and recording of soil pollution are combinations of various methods and techniques. The most important individual steps are given in Figure 20.

Figure 20. Individual steps of object-related procedures for detection and identification of soil contaminants

Sampling has a central importance in this process (see also, ⟶ Sample Preparation for Trace Analysis). All other individual steps of investigation processes depend on planning and performing of sampling. Compared with the endeavour and successes in the field of chemical and instrumental analysis, the sampling, but also the sample pretreatment for the preparation of a representative laboratory sample, have up to now been underestimated.

For international harmonization of test standards the ISO has undertaken the task of collecting the national standards for soil investigations, and — after thorough tests, improvements, and adaptations to the current state of analysis — of introducing them into international ISO standard. The Technical Committee “Soil Quality” (ISO TC 190 – Soil Quality) has already submitted standards for numerous test methods, including methods for sampling and sample pretreatment. A basic valuable reference compendium is the German *Handbuch der Bodenuntersuchung* [347] (“Handbook of Soil Investigation”), in which national and international standards, methods and rules in the field of soil investigations have been collated in abridged version in order to update this collection continually.

6.1.2. *Sampling*

Sampling is the first and most important step of soil investigation procedures. Not only the quality of the test data but also decisions that can have far-reaching consequences at many levels (economic, health, and environmental policy) depend on the well-designed planning and careful performing of sampling. The soil sample once taken is seldom reproducible with respect to its chemical and physical composition, i.e., a second sample from the same sampling point may not be identical.

The basis for the development of an object-related sampling strategy is the definition of the objective of the investigation, i.e., the future use of an area, taking into account all site-specific features that should be protected. If knowledge about the nature, position, and extent of soil pollution is lacking or inadequate, a preliminary investigation is required. In the preliminary investigation sampling points are rather randomly selected and smaller in number: both selection and number of sampling points must suffice to delimitate spatially the area under suspicion. Information about previous uses of the land or soil and about material inputs and their paths is very helpful in this phase. If the suspicion of soil pollution is confirmed, the sampling for the detailed investigation has to be planned.

For this, criteria according to DIN ISO 10381–1/4 [348], which are listed in brief below, have to be observed:

1. *Definition of the sampling site*
   The sampling site is delimitated and defined, taking into account the nature of the relevant substances and their lateral spread and vertical distribution. This information has been obtained in the preliminary investigation.
2. *Selection of sampling patterns and sampling points*
   Sampling patterns can be based on
   - Known “hot spots” and substance distribution
   - Distribution along a line
   - Strip-wise distribution
   - No specific estimation of substance distribution

   The design of patterns includes the setting up of single sampling points to complex patterns developed on the basis of statistical and computer-aided methods.
   The following patterns can be taken [348], [349]:
   - Systematic sampling (regular grids), e.g., sampling on a circular grid or triangular grid; sampling along a linear source
   - Nonsystematic (irregular) sampling, e.g., random sampling; stratified random sampling, unaligned random sampling

   The location and the number of sampling points in the site depend on the aim of investigation and the results of preliminary studies.
3. *Selection of the test parameters*
   Depending on the objective, the test parameters are selected in accordance with the results from the preliminary investigation.
4. *Single or composite samples*
   Single samples are necessary during the preliminary investigation to characterize the heterogeneity of the soil, to delimit the contaminated area, and to determine the vertical substance distribution. Single samples are taken from one sampling point. Composite samples are individual samples from different sampling points but from the same sampling depth. It has to be determined for each individual case which single samples shall be combined to give composite samples.
5. *Number of samples*
   The number of samples of one site follows from the results of preliminary investigation and is linked with the objective of the investigation. Because of the general complexity of the sampling, it is advisable to take more single or composite samples than are required for the laboratory investigations. The reserve samples can be investigated subsequently on request.
6. *Sampling from disturbed or undisturbed soil stratification*
   For most laboratory tests for soil pollutants, sampling from disturbed stratification is sufficient. For certain soil-physical and soil-biological parameters, a sampling from undisturbed stratification is necessary. For this, the arrangement of soil prospecting (trial pits) can also be useful.
7. *Sampling equipment*
   Depending on the problem, various equipments or techniques be used, such as hand or power augers, percussion drilling systems, tube borers, but also mobile hydraulic drilling systems. For sampling from undisturbed stratification, metal cylinders and cutting frames (e.g., for sampling of forest soils) are used. DIN ISO 10381–2 [350] contains an assortment of the techniques concerned. Cross contaminations of the samples by abraded metal and by transfering of soil material from sample to sample, must be avoided.
8. *Sampling depth*
   The sampling depth depends on the type of soil use, but can also relate to the particular route of effect for special kinds of acceptors (e.g., children's playgrounds). In cultivated soils, samples are usually taken from the top soil, i.e., to a depth of 20 – 30 cm for arable soils and to a depth of max. 10 cm for pasture soils. In uncultivated soils, samples are usually taken to a soil depth of max. 10 cm. For refilled sites and in analogous cases, sampling by soil layers is appropriate.
9. *Sample quantity*
   The sample quantity per sampling point and layer is determined by the kind and size of the laboratory investigation, the condition of the soil material (e.g., mineral grains, sand, pebble, or foreign materials), and required reserve samples. For chemical analysis 500 g of fine soil should be obtained.
10. *Use of containers*
    The containers must ensure that the sample material is not contaminated by foreign substances and that no losses or changes of material occur by adsorption, volatilization, or degradation processes. For soils containing organic pollutants, glass vessels with tight closures should be used. For preserving soil samples after sampling on the spot, cooled transport containers are useful. They should be used for samples whose constituents to be tested are volatile or degradable. The soil samples can also be temporarily stored cool in these containers for a limited time. The sample should be clearly and unmistakably labeled on both the container and its lid.
11. *Safety precautions*
    The personal protection of the sampling staff also has to be included in the sampling strategy [351].
12. *Sampling report*
    The sampling report should contain the following informations [348]:

Description of site and surrounding area, time of sampling
Cartographic sketch of the area and the sampling points
Execution of the sampling in all details
Deviations from plan and their cause
Delivery to the laboratory

The quality of the sampling and of the reporting is closely related to the sampling staff. It has to be ensured that the sampling, as a decisive quality parameter of the laboratory data, does not put that data in question. Qualification and advanced training of the sampling staff are therefore of utmost importance.

6.1.3. *Sample Pretreatment*

After their entry into the laboratory or after appropriate temporary storage, soil samples are usually pretreated for analysis in various ways, depending on the analytical problem.

Like sampling, the sample pretreatment also is a step of the analytical method, to which little attention often is paid, yet which nevertheless can contribute considerably to the total error of a method. Especially, contamination or losses of materials to be tested must be avoided or minimized. Contamination can arise, e.g., during mechanical size-reduction by grinding devices as well as by the carry-over of soil material. Material losses or changes often occur through inappropriate drying procedures, the effects of light, prolonged periods of storage, or change of storage conditions.

It is advisable to pretreat the whole field sample. The sample is dried sometimes after preceding manual or mechanical preliminary size-reduction with sieves. A mild thermal drying is carried out at up to 40 °C. Freeze-drying is to be preferred for tests on organic compounds (see Section Analysis of Organic Soil Pollutants) as well as on volatile inorganic substances (e.g., mercury). For this, though, the often large initial sample has first to be reduced, because the capacity of the freeze-drying units is often limited.

After drying, the whole sample is mechanically size-reduced. For sample material from the freeze-drying size-reduction is sometimes not necessary.

Afterwards, sample division is advisable if reserve samples have to be formed. This is performed in mechanical sample-dividers, because manual sample division is not without errors.

To prepare the laboratory sample ready for analysis, the size-reduced soil material is sieved to obtain different grain-size fractions. In general, fractions with a grain size < 1 mm are used for the laboratory sample. Other grain fractions are, however, also customary. Sieving to definite grain sizes is performed to obtain samples of the same chemical and physical composition, and also for improving the extraction yield in the analysis.

During the storage of dried soil samples, the soil reabsorbs water, depending on the room temperature and humidity. The water content of so-called air-dried samples is usually about 3 – 5 %. In individual cases a further drying can be required. An DIN ISO standard exists for the handling of samples [352]. The laboratory is in charge of the correct care during sample pretreatment. Documentation of the laboratory operations is mandatory for reasons of quality assurance.

6.1.4. *Sample Preparation*

The sample preparation is usually the first individual step of an analytical method and an important part of combined analytical methods. Its objective is

1. To separate the elements/compounds to be tested from interfering matrix constituents and to convert them into a form accessible to the measurement (e.g., aqueous solution)
2. To render low substance concentrations (ng/g or lower) detectable or determinable by preconcentration steps

In the case of instrumental direct methods (e.g., X-ray fluorescence), this preparation is omitted; at the most, melt digestion is used. The relatively low power of detection of direct methods is disadvantageous [353]. Wet-chemical combined methods, on the other hand, enable the use of various measuring systems as well as simple calibration by aqueous standard solutions (⟶ Trace Analysis – Methods of Modern Trace Analysis).

Systematic sources of error can originate from contamination of equipment, vessels, and reagents (blank values), as well as from the working environment (laboratory air). Material losses occur through volatilization and adsorption.

The digestion techniques are becoming increasingly powerful, because of their degree of automation, ensuring optimal decomposition conditions. Consequently they are more economical than previous techniques, e.g., because of higher sample throughput. In principle, the following modes of processing can be used:

1. Digestion
2. Extraction
3. Elution

In *inorganic analysis* the terms digestion and extraction are frequently used synonymously. According to the recent ISO methods, *digestion* means the total digestion of soils, but also of geological samples with the aid of strong acids (mixtures). The digestion yield should amount to 100 %.

The term *extraction* means that relatively weak acids, acid mixtures, complexing agents, neutral salt solutions, etc. are applied. Extraction is used when relatively low material yields can be tolerated or a certain element fraction or form of element binding (e.g., plant-available compounds, exchangeable cations) has to be determined selectively. Environmentally relevant material mobilities in soils can be characterized approximately by various extractants. Figure 21 shows the corresponding relationships. Extraction is usually used for the detection of organic substances in soils.

Figure 21. Relations between the state of mobility of heavy metals in soils and state-related digestion or extraction solutions [354]

DTPA = diethylenetriaminepentaacetic acid; EDTA = ethylenediaminetetraacetic acid

The *elution* of soil contaminants is frequently carried out from the standpoint of groundwater management. However, elution with water, which is still practiced today, is very controversial, since the significance of the results can fluctuate greatly owing to considerable influences from the soil matrix.

For sample preparation for the detection of *inorganic substances* in soils, high-performance digestion techniques are available today that enable an efficient, low-cost, environmentally compatible, and largely low-error operation:

1. Wet digestion (extraction) by means of open systems with convective heat transfer (heating block, reflux) [354]; closed high-pressure digestion techniques [355]; or microwave technique [356], [357]
2. Dry decomposition [358] by means of combustion systems such as pressureless decomposition in open systems [flask combustion (e.g., Schöniger digestion), Wickbold combustion with oxyhydrogen gas flame], cold-plasma ashing and dry ashing or melt digestion.

Of the wet-chemical digestion techniques, the microwave technique is becoming increasingly important. It is time-saving, environmentally compatible and, with regard to the reproducibility of the material yield, often more favorable than, e.g., pressure digestion techniques.

For the determination of *organic compounds* in soils, there are standard procedures for the preparation of measuring solutions. The separation processes are based on partitioning processes between phases, which obey physicochemical laws. For organic soil pollutants the following technical processes are available in routine analysis [359], [360]:

1. Head-space processes (⟶ Gas Chromatography – Static and Dynamic Head Space Analysis) for highly volatile halogenated hydrocarbons and aromatic hydrocarbons (benzene, toluene, xylenes) that are also suitable for difficultly vaporizable and polar compounds after converting them to suitable derivatives
2. Soxhlet extraction for low-volatility halogenated hydrocarbons
3. Extraction with supercritical fluids (SFE) as a relatively new process route for the detection of PAHs, PCBs, and pesticides in soils

In individual cases, preconcentration steps are sensible and necessary in order to determine the true substance concentration (e.g., preconcentration by ion exchange or in cartridges).

6.1.5. *Measurement*

Inorganic Substances. Inorganic soil pollutants, which are found matrix-free and without interfering accompanying substances in the measuring solution, can be determined by different instrumental methods. Of these, atomic absorption spectrometry (AAS, ⟶ Atomic Spectroscopy – Atomic Absorption Spectrometry) and its various special techniques are used most widely:

1. Flame technique for alkali metals and heavy metals (F – AAS)
2. Graphite furnace technique (GF – AAS) for determining elements in the lower ng/g range
3. Hydride technique for hydride-forming elements such as As, Se, or Sb
4. Cold vapor technique for mercury

All of the techniques are used widely in soil and environmental analysis, depending on the kind of element and its concentration and on the desired sensitivities of detection. Correction of the nonspecific background by deuterium or Zeeman compensation leads to improvement of the data in the trace and ultratrace range [361].

Atomic emission spectroscopy with inductively coupled plasma impulse (AES – ICP, ⟶ Atomic Spectroscopy – Inductively Coupled Plasmas) is already widely used in the routine

analysis of inorganic substances in soils because of its great technical advantages. The important advantages include high measurement frequencies and the simultaneous determination of several elements. Disadvantages are at present relatively low sensitivities of detection. However, measurement of most relevant elements (with the exception of cadmium, mercury, and thallium) is possible because of their relatively high geogenic background contents. With AES – ICP, survey analyses for a wide range of elements in unknown samples also can be carried out.

The flow injection analysis (FIA) is applied with the mentioned AAS systems to improve analytical and economical aspects by automation of, e.g., sample introduction, dilution or preconcentration, or addition of internal standards [361].

For element measurement other techniques exist, not or scarcely inferior in their specificity and sensitivity of measurement to the AAS methods, but less widely used in routine analysis for the detection of soil pollutants. They include electrochemical methods (e.g., polarography, voltammetry) and molecular spectroscopic methods (e.g., UV/VIS spectroscopy). Multielement determinations also are possible with X-ray fluorescence spectroscopy after melt digestion.

Organic Compounds. The determination of organic compounds in polluted soil samples is performed according to the following process steps [359]:

1. Chromatographic separation
2. Detection
3. Evaluation

The *vapor-phase separation* of organic substances is today carried out mainly in capillary columns, usually with high resolution and sensitivity. Substance-specific separating columns are used, e.g., for the analysis of PAHs and PCBs. Aside from the “miniaturization” of separating columns, further advances in the separation of substances are emerging in connection with the development and adaptation of microchips and chemosensors [360].

Many substance- and structure-specific detectors are suitable for the detection of organic compounds. Examples are flame-ionization detectors (FID), thermionic detectors (TID), or electron-capture detectors (ECD) (⟶ Gas Chromatography – Detectors). The coupling of gas chromatography with mass spectrometry (GC – MS) offers an improved sensitivity of detection as well as a reliable identification of individual compounds or substances.

High-performance liquid chromatography (HPLC) has developed into one of the important and efficient separation techniques for environmental analysis [362]. This technique enables the determination of difficultly vaporizable, thermally labile, or ionogenic substances in extracts or eluates. Columns both for general uses (e.g., in reversed-phase chromatography) and for special applications (e.g., for the determination of PAHs) have a high degree of standardization with good reproducibility. Improvements in detection are possible with the photodiode array detector, which permits simultaneous measurement at different wavelengths. Coupling techniques with the mass spectrometer (HPLC – MS) having the same effects as those of GC – MS are awaited.

6.1.6. *Evaluation*

Instrumental measuring systems are generally equipped with microprocessors and computers. The equipment is used for controlling apparatus and operating parameters as well as the entire procedure from the input of the sample up to the documentation of the measurement signals. Editing, processing, and documentation of the data — as far as to adoption in dispatchable test certificates and in data banks — become more and more computerized. Interfaces allow the individual measuring systems to be included in networks such as the laboratory information and management system (LIMS). This makes it possible to record all information on sampling and sample pretreatment.

6.1.7. *Quality Assurance*

Analytical data are basically subject to error. Systematic and random errors result from the various process steps, from sampling to measurement. While errors during the individual analytical steps can more easily be identified, minimized, or eliminated, little is yet known about sources of error in sampling and sample pretreatment and their proportion in the total error, or the analyst may often not be conscious of them.

The inhomogeneity of contaminated soil samples is unquestionably the most frequent cause of a sometimes high systematic error. Therefore, as already explained in Section Sampling, the sampling on the spot has to be carried out very carefully. In all later steps — from the immediate storage in containers on the spot, via transport, to the conclusion of the sample pretreatment — the minimization or elimination of errors is more easy if the sampling standard operation procedures (SOP) are exact and obeyed. The documentation of the sampling in all its details is very important here.

Features of the procedure such as selectivity, accuracy, and precision as well as limits of detection and determination are indispensable for the statistical evaluation of analytical procedures [363]. Often they have still to be worked out.

Quality assurance systems should comprise the following main issues:

Sample and laboratory management
Quality assurance manual according to DIN EN ISO 17 025
Participation in round robin tests
Staff qualification
Maintenance of equipment
Sample handling
Methodology
Statistic control
Recording and reporting of data

The realization of these requirements is the basis for the competence and reliability of the laboratory carrying out the test. It is therefore recommendable to entrust with the investigation of soils only such test laboratories as meet all conditions mentioned.

6.1.8. *Analytical Procedures for Selected Inorganic and Organic Soil Pollutants*

From the multiplicity of analytical procedures for determining soil pollutants in this section detailed procedures are described for the elements cadmium and thallium as well as for PAHs and petroleum hydrocarbons. These are analytical procedures that are already far advanced in their degree of standardization — thus the extraction of trace elements soluble in aqua regia (DIN ISO 11 466), the measurement of cadmium and other elements by F – AAS and GF – AAS (DIN ISO 11 047).

First drafts for national or international standardization are available for the extraction of mobile trace elements from soils with ammonium nitrate solution (DIN 19 730) and for petroleum hydrocarbons (ISO TR 11 046).

6.1.8.1. *Analysis of Cadmium and Thallium*

Both heavy metals occur ubiquitously in soils, although cadmium is more widespread than thallium, which has a more local importance. They are nonessential trace substances which, however, have toxicological relevance because of their mobility behavior in soil – plant transfer and their enrichment capacity in food and forage plants. Previously only the so-called total content after extraction with aqua regia or equivalent acid mixtures was used as the basis for evaluation, this is today supplemented by the determination of that part of the total content which is mobile, i.e., short- or mediumterm available by plants or translocatable by percolate water into deeper soil layers (leaching).

6.1.8.1.1. Sample Preparation

According to DIN ISO 11 466 *cadmium* is extracted from air-dried fine soil (grain size <0.1 mm) with aqua regia under reflux for a mean duration of ca. 2 h. The supernatant suspension (filtrate) in the measuring flask after sedimentation of the undissolved fraction is ready for measurement. A detailed description is given in [364].

Owing to the formation of volatile thallium compounds, HNO_3 and H_2O_2 are used as an extraction mixture for the determination of *thallium* [365]. Pressure digestion systems should be used, with closed vessels of PTFE (polytetrafluoroethylene), PFA (perfluoroalkoxy resin) or other suitable materials and with thermal heating devices or with microwave heating systems. Undissolved substances must immediately be removed from the extraction solution, since otherwise deficiency of the true concentration is possible.

The extraction with *ammonium nitrate* detects nearly all environmentally relevant trace elements, including cadmium and thallium, in one solution. The mobile element fractions, i.e., those available or leachable in a short time, are determined. Extraction is carried out by shaking overhead at room temperature. After the filtration, the extract is stabilized with HNO_3.

6.1.8.1.2. Measurement

In instrumental analysis, the relevant heavy metals are determined with, among others, F – AAS, electrothermal AAS (ET – AAS), and AES – ICP, which are part of the basic equipment of laboratories working in environmental analysis. Other measuring systems will consequently not be discussed.

Flame AAS and electrothermal AAS are described in detail in DIN ISO 11 047. They differ above all in the sensitivity of detection for the elements named therein. Thus with expected cadmium contents >2 mg/kg soil, the use of F – AAS is recommendable and with contents <2 mg/kg soil that of ET – AAS.

Because the thallium contents in soils usually are very low, ET – AAS (graphite tube furnace) and appropriate background compensation (e.g., Zeeman method) are recommended for the measurement [365].

The same instrumental systems can be used for the measurement of the heavy metal contents from the ammonium nitrate solution. Since the elements often occur in very low concentrations in these extracts, measurement with GF – AAS is advisable. At higher assumed contents, F – AAS also can be used. Efforts to determine cadmium concentrations also with AES – ICP have at present not yet reached the routine stage, because here the sensitivity is still unsatisfactory.

Taking into account instrumental equipment, extraction agents, and laboratory staff, the following limits of determination specific to different procedures can be assumed (Table 31)

[347].

Table 31. Limits of detection of different AAS methods with respect to cadmium and thallium [347]

Element	F – AAS, mg/L	GF – AAS, µg/L	AES – ICP, µg/L
Cadmium	0.02	0.1	10
Thallium	0.2	2	100

Information is at present still being compiled on procedural characteristics, such as precision and accuracy.

6.1.8.2. *Analysis of Organic Soil Pollutants*

In this chapter the analytical methods for the determination of two typical organic soil pollutants, PAHs and petroleum hydrocarbons are presented.

6.1.8.2.1. Analysis of Polycyclic Aromatic Hydrocarbons

Polycyclic aromatic hydrocarbons occur ubiquitously in the environment (see Section Polycyclic Aromatic Hydrocarbons (PAHs)). While previously their main anthropogenic source originated from coal combustion and coal processing, today they are mainly emitted by scattered sources, such as motor vehicle traffic, or domestic fuel.

The EPA has stipulated 16 PAHs — some of which are suspected of being carcinogenic — in its “priority pollutant list” for monitoring and restriction (see below):

Naphthalene	($C_{10}H_8$)
Acenaphthylene	($C_{12}H_{10}$)
Acenaphthene	($C_{12}H_{10}$)
Fluorene	($C_{13}H_{10}$)
Phenanthrene	($C_{14}H_{10}$)
Anthracene	($C_{14}H_{10}$)
Fluoranthene	($C_{16}H_{10}$)
Pyrene	($C_{16}H_{10}$)
Benz[*a*]anthracene	($C_{18}H_{12}$)
Chrysene	($C_{18}H_{12}$)
Benzo[*k*]fluoranthene	($C_{20}H_{12}$)
Benzo[*b*]fluoranthene	($C_{20}H_{12}$)
Benzo[*a*]pyrene	($C_{20}H_{12}$)
Indeno[1,2,3-*cd*]pyrene	($C_{22}H_{12}$)
Dibenzo[*a,h*]anthracene	($C_{22}H_{14}$)
Benzo[*g,h,i*]perylene	($C_{22}H_{12}$)

After extraction with an organic solvent PAHs are determined by capillary gas chromatography with mass-selective detector (quadrupole or ion trap). In addition HPLC with fluorescence detection (FLD) is becoming increasingly established [347], [368-371].

The ISO has published in the Technical Committee 190 “Soil Quality” a draft (ISO/CD 13 877) on the analysis of the PAHs [372].

Samples from lightly loaded and heavily loaded soils are prepared differently. *Lightly loaded soils* are extracted with acetone. The extracts are purified by mixing with cyclohexane, extraction of acetone with water, and subsequently purification via an aluminum oxide column.

The *heavily loaded soils* are extracted with toluene in a Soxhlet apparatus, and the PAHs measured, without further purification, with an HPLC – FLD or diode array detector (DAD) (⟶ Liquid Chromatography).

In the case of lightly loaded soils the purification is labor-intensive, while in the second method, only one Soxhlet extraction taking 4 – 8 h is required.

A HPLC method [373] has been developed to improve the efficiency of the extraction process, its reproducibility, practicability, profitability, industrial safety, and environmental compatibility. In this method an ultrasonic extraction is performed with tetrahydrofuran or acetonitrile, and a purification carried out on hydrophilized silica gel [373].

Samples for gas chromatography (GC) are subjected to a Soxhlet extraction with toluene. Purification is carried out on silica gel or aluminum oxide.

Because of the sample preparation by air drying which is generally used, the measurements for low-molecular PAHs are unreliable. This applies particularly to the four easily volatile components of the EPA list, naphthalene, acenaphthylene, acenaphthene, and fluorene. To avoid these possible losses, the mild freeze-drying method should be used preferably [374]. In this technique the samples are dried at ca. –40 °C under vacuum.

Other laboratories use a cold acetone – cyclohexane mixture for well homogenized, fieldfresh samples. The measurements are made with HPLC – FLD or – DAD, or GC – MS. This method was developed and validated in collaboration with state and private laboratories for the analysis of soil, waste, and contaminated site samples [375].

Immunoassay test methods have also been offered as screening processes [376].

The use of SFE is also customary for soil samples (see Section Sample Preparation). In this, supercritical carbon dioxide is passed through the sample at high pressure. The carbon dioxide is subsequently depressurized and collected in a solvent receiver. The advantage of this method is the low solvent requirement and short extraction times. An obstacle to routine application is the different extraction yields under the same process conditions but different soil samples. An optimized method must be developed here for each type of soil [377-379].

6.1.8.2.2. Petroleum Hydrocarbons

The risk of pollution exists anywhere where petroleum hydrocarbons are processed, stored, reloaded, transported, or used [380].

In some countries standards and draft standards exist for the determination of petroleum hydrocarbons in soils [381], [382].

In the extraction of petroleum hydrocarbons since 1981, carbon tetrachloride (which had usually been used up to that time) has been dispensed with for reasons of industrial safety in favor of 1,1,2-trichlorofluoroethane. However, the use of chlorofluorocarbons (CFCs) is controversial because of their ozone-depleting effects in the atmosphere. Whether CFCs will be available in the future for analytical purposes is therefore uncertain.

For quantitative determination of petroleum hydrocarbons an *infrared spectrum* is recorded from wave number 3125 cm^{-1} to 2800 cm^{-1}. The CH_2 absorption band, the CH_3 band at 2925 cm^{-1}, the CH_3 band at 2958 cm^{-1}, and the aromatic CH absorption at 3030 cm^{-1} are used for quantification.

An alternative to this is offered by a *GC – FID method*, whereby the total area of the peaks from decane ($C_{10}H_{22}$) to *n*-tetracontane ($C_{40}H_{82}$) is evaluated as petroleum hydrocarbons content.

The ISO TC 190 “Soil Quality” has submitted a draft technical report [ISO/TR 11 046: 1994 (E)] [382]. The procedure recommends a shaking method or a Soxhlet extraction with 1,1,2-trichlorofluoroethane. The “clean-up” step uses a column filled with magnesium silicate or aluminum oxide.

The validity of the aforementioned GC method has been checked by an interlaboratory comparison. According to this the difficulty of the procedure is in the external calibration with a petroleum standard whose petroleum hydrocarbon distribution does not in every case agree with that of the soil sample. Sample injection is the largest source of error in the procedure. Split or splitless injection (⟶ Gas Chromatography – Split Injection) techniques should not be used in any case. The results determined with the GC method should be supported by means of IR [383].

With the draft method 3560/8440 [384] the EPA has proposed an extraction with *supercritical carbon dioxide*. The sample is dried with magnesium sulfate before the extraction. The SFE is carried out at 80 °C and 34 MPa. Tetrachloroethylene is used as collection solvent. The “clean-up” is carried out with a silica gel column or a solid-phase cartridge. The SFE

method is equivalent to a Soxhlet extraction in respect of reproducibility and recovery.

Accelerated solvent extraction (ASE) is a newer development. Conventional solvents are used at up to 200 °C. In order to maintain the solvent in the liquid state above its atmospheric boiling point, the extraction is carried out at 0.3 – 20 MPa in pressure-tight tubes [385], [386].

Outlook. In soil analysis, the development of digestion procedures, extraction procedures, and methods of measurement is aimed at efficiency, as much automation as possible, and at little solvent consumption.

Soil sampling remains the most relevant area for accuracy because it is subject to relatively large errors. Inaccuracy of the analytical values caused by the sampling can only to a limited extent be compensated by improving the analytical procedure [387].

6.2. Evaluation Concept

6.2.1. *Uptake Paths to Humans*

The hazard potential of pollutant-containing soils to humans is normally assessed from a number of different basic conditions. In the foreground — aside from the investigation of the nature and concentration of the pollutants in the soil — are principally the uptake paths (possibilities of transfer) by which pollutants can enter the human body. In addition the present use of the soil areas is important, because conclusions can be drawn from this on predominant uptake paths or special exposure situations. The relevance of the pollutant contents of the soil can only be assessed by considering all these parameters. On the other hand, the evaluation of pollutant concentrations on the basis of clinical-toxicological data alone without reference to the soil environment must be rejected as inadmissible [388].

6.2.1.1. *Inhalation Uptake*

Nonvolatile Pollutants. The uptake of particle-bound, nonvolatile pollutants is always assumed when fairly large parts or even the whole of a contaminated site have no vegetation or other kind of cover (e.g., asphalt). The lack of vegetation is observed relatively frequently on foundry heaps in which high concentrations of phytotoxic metals are present [388]. Here dust can be blown up and subsequently inhaled by human beings.

The uptake by inhalation depends on the concentration, exposure time, substance-dependent toxic effect, and especially on the particle size. The fine dust (particles with an aerodynamic diameter of 1 – 7 µm) which can pass into the alveoli must be regarded as especially biologically relevant. These dust particles reach as far as the pulmonary vesicles. From there easily absorbable toxic agents can pass directly into the bloodstream.

It can be presumed from literature data that hazardous effects on humans as a result of the blowing-up of dusts are encountered only very rarely [389]. Effects on humans have to be assumed chiefly when there is an active release of dusts from contaminated material, e.g., during activities on sports grounds with surface made of blast-furnace ash or on leisure grounds in the vicinity of contaminated sites. In dry weather, these activities can result in severe dust formation. This leads to a potential hazard not only for the participants themselves, but also for spectators or neighbors [390].

Volatile Pollutants. The uptake of volatile pollutants from gas emanating from the soil is considerably more important than the inhalation of particles. In the case of volatile pollutants, a genuine exposure of residents and users of contaminated sites and people living nearby is frequently demonstrable [391].

The exposure to gases or vapors from contaminated sites is possible when, for example, a building is constructed directly on the contaminated soil. Taking into account that residents stay up to 24 h a day in the polluted area, a considerable uptake of pollutants is certainly possible. But even people living near contaminated sites can be at considerable risk as a result of the migration of gases and vapors beyond the immediate area of the contaminated site. However, the concentrations of the volatile pollutants are usually less in the neighborhood than directly on the contaminated site itself. The possible accumulation of gas in indoor air is particularly relevant. The occurrence of odor nuisances and/or the detection of methane and carbon dioxide in cellars of buildings on contaminated sites is always a indication of this risk [392].

6.2.1.2. *Oral Uptake*

The risk of oral uptake of pollutants from the soil appears to be greatest for young children. Many authors report an oral uptake, above all of heavy metals by hand-to-mouth activity, but give no information on the amount of dust or soil thereby ingested. Estimates in the literature are in a range between 200 mg and 10 000 mg of soil per day. Generally it is assumed that children at play take up 200 mg to 1000 mg of soil per day. Taking this amount as the basis for children aged three to five years, the uptake of pollutants via the soil plays an important part for this group when compared with the other contamination paths and must definitely be taken into account in the estimates of effect.

The oral exposure for adults originates in most cases from the uptake of contaminated edible plants from backyards or garden plots. The uptake of heavy metals by plants has been proved in a large number of studies. As a result, the agricultural use of lands in the neighborhood of heavy-metal emitters has been restricted. Aside from the uptake of pollutants present in the soil via the roots, additional contamination of the plants can occur by deposition of pollutant-containing dust.

The direct oral uptake of pollutants by adults from the soil of backyards and garden plots can be rated as negligible. The danger to small children is certainly considerably less than that of playgrounds, because the use of backyards and garden plots, especially for the cultivation of fruit and vegetables on patches, usually allows no play activities that could lead to noteworthy contamination.

Another exposure path for oral uptake of pollutants can be contamination of groundwater, which frequently occurs at contaminated sites. However, the problem is not the public supply of drinking water of adequate quality, but rather the possible use of contaminated groundwater from domestic wells [390].

6.2.1.3. *Uptake via the Skin*

The contamination of the skin has to be rated as rather unimportant. The theoretically possible uptake of fat-soluble substances or solutions by direct contact with the skin requires very high pollutant concentrations, such as are not normally found on the surface of contaminated sites or other contaminated soils. The absorption of gas or vapor via the skin must be rated as almost impossible even under extreme exposure conditions and can therefore be ruled out in this context [389].

6.2.2. *Relevant Soil Uses*

To enable an evaluation of soil contamination with regard to the health hazard for persons concerned and for the establishment of tolerable soil values, it is reasonable to reduce the huge number of possible uses of the soil to a small number of use scenarios. Starting points could be on the one hand particular user groups (playing children or young people, sportsmen and sportswomen, garden plot holders, etc.) and on the other the complex uptake paths of nonvolatile or semivolatile substances (predominantly oral uptake, mixed inhalation and oral uptake, etc.). It does not appear sensible to consider all possible transfer modes from the soil to humans in detail but rather to use simple models and scenarios as a basis for a general assessment. Table 32 shows use scenarios according to the assessment system of EIKMANN and KLOKE with parameters characterizing use and protected subjects [393].

Table 32. Use criteria for various types of soil use (objective: protection of humans)

Type of use	User group/ protected subject	Uptake path	Soil areas	Soil depth
Children's playgrounds	small children and escorts	oral	sand pits vegetation-free environment	35 cm
Backyards and garden plots	children adults	oral by inhalation	patches low-vegetation areas	35 cm
Sports and recreation grounds	sportsmen and sportswomen young people	 by inhalation	gravel surfaces vegetation-free areas	10 cm
Parks and leisure grounds	adults children	oral by inhalation	unpaved, low-vegetation areas	10 cm
Industrial and commercial areas	adults of working age	by inhalation water path	unpaved, vegetation-free areas	10 cm

6.2.3. *Evaluation Criteria*

In the development of regulative values or values for the soil, there is always a need to establish conventions, for example, for the comparability of measurement methods and of measurement results. Although these conventions are certainly based on scientifically supported knowledge, they are nonetheless to be regarded within a certain tolerance range as “arbitrary”.

The calculation of tolerable soil values depends to a considerable degree on the particular conventions chosen. The influence of these conventions on the quantification of the uptake is clearly greater than that of toxicologically derived criteria (body loads). Moreover the tolerable soil values calculated as a function of the chosen assumptions on exposure are frequently far above or far below the usual background concentrations of these substances in soils.

In the assessment methodology, owing to the considerable uncertainties and difficulties which have been described, there is a trend of describing the exposure — especially of persons on contaminated soils — by characteristic simplified individual scenarios for types of use and protected property and of establishing a quantitative assessment on this basis or to orient oneself according to the main uptake path. Thus the base values (BW I) stated by EIKMANN and KLOKE for (harmful) substances in soils are derived essentially from the corresponding background concentrations in the soils in Germany. The tolerance (test) values (BW II) and intervention values (BW III) are defined as a function of the toxic properties of the substances involved and the specific exposure situation (inhalation) by application of appropriate factors [393].

Other evaluation models (e.g., the EPA model or the Holland List) attempt to avoid these methodical difficulties. Here, either the risk is estimated by using evaluation models referring to individual cases without defining soil values; or for defining acceptable soil values, only difficultly understandable correction factors or so-called reliability scores are applied. In addition, all estimation parameters used in these models (e.g., according to information from the authors of the Holland List) have uncertainties that frequently can amount to a factor of 10 or more [394].

The repeated demand for “strictly toxicologically derived” soil values, taking into account the various kinds of soil use, cannot be satisfied owing to the paramount influence of the conventions chosen for quantifying the (inhalation) uptake of pollutants. When different evaluation models are applied in the context of an individual-case assessment according to the classical derivation model, this can result in the definition of different soil concentrations for a certain pollutant. However, different intervention or remediation target values, depending on the particular contaminated site, are certainly unacceptable. In particular the frequently existing necessity for immediate action — in relation to a further possible use of contaminated soil areas — requires at least the definition of (standardized) intervention values. In addition, different remediation target values for the same kind of uses will certainly not be accepted by the public because of the incomprehensibly higher remediation costs in single cases.

In the preparation of balances for the transfer of pollutants from the environment to humans the pollutant contaminations of the various environmental media (atmospheric and indoor air, drinking water, and food) are considered. No attention is usually paid to the direct exposure from the soil, because it must be rated unimportant in relation to the total uptake. The indirect uptake from the soil via food plants and animals is normally taken into account by recording the contamination of the food [395].

The direct intake of pollutants from the soil — which is frequently considered the main problem of contaminated sites — is a very specific pollution problem for only part of the population, and therefore also cannot be considered in a general balance. If tolerable body doses are reached or exceeded as a result of the general environmental pollution with particular pollutants, such as heavy metals, in theory also a reduction of the soil contamination can be considered to lower the metals content in the environment. However, because of the practically nonexistent discharge from soil and the nondegradability of metals, a reduction cannot normally be achieved here, by contrast, e.g., with air (by reduction of emissions). An inclusion of the soil in such balances as an equivalent medium appears therefore to be unjustified and leads to an assessment dead-end [396].

Extensive contamination of the soil by heavy metals (caused by immissions) frequently occurs, especially in the conurbations, and, in the use of garden plots or backyards, results in (officially recommended) restrictions of the cultivation of various useful plants. This is one of several possibilities of reacting to such wide-ranging soil contamination. On the other hand, an extensive remediation of the soils of whole regions to achieve tolerable heavy metal concentrations must certainly be regarded as difficult, if not quite impossible. For the purposes of general soil protection (above all also for the persistent organic compounds), any further input must rather be kept as small as possible.

7. Remediation of Soil and Land

Volker Franzius, Detlef Grimsky, Norbert Möhlenbruch, Ulf Dworshak

7.1. Remediation Methods

7.1.1. *Introduction*

The effects of point sources polluting soil and groundwater are particularly obvious when regarding the problem of contaminated sites. Based on the importance of this problem during the 1980s, administration, industry and commerce have equipped themselves with strategies and techniques to solve it. The methods for soil purification described in this section mainly relate to the remediation of contaminated sites. Application of remediation processes to the treatment of extended soil contaminations caused by airborne emissions or agricultural measures will not be treated.

As of October 31, 1998 about 238 000 suspected contaminated sites were registered in Germany (Table 33), divided into about 100 000 abandoned waste disposal sites and about 138 000 abandoned industrial sites. In addition, registration has been carried out for about 34 000 suspected contaminated sites on 1026 military properties, that had been used by the former West Group of the Soviet Troops (WGT) in East Germany and 3240 suspected former armament sites (status 1995). Altogether about 10 000 properties used by the military are being examined for suspected contaminated sites. The number of actual contaminated sites is uncertain because the risk assessment which follows the registration has not yet been completed for the whole area of Germany. On a cautious forecast, about 10 % of suspected contaminated sites are expected to be contaminated and to require some remediation. As a rule, suitable remediation measures for individual cases can be put into concrete terms only after risk assessment.

Table 33. Suspected contaminated sites in Germany*

Berlin	673	5541	6214
Brandenburg	5585	8580	14 165
Bremen	105	4000	4105
Hamburg	460	1701	2161
Hesse	198	160	358
Mecklenburg-Westpommerania	4332	7462	11 794
Lower Saxony	8957	n.a.	8957
North Rheine-Westphalia	17 155	14 874	32 029

Saarland	1801	2442	4243
Saxony	9382	22 197	31 579
Saxony-Anhalt	6936	13 295	20 231
Schleswig-Holstein	3076	14 497	17 573
Thuringia	6192	12 368	18 560
Germany total	**100 229**	**137 798**	**26 038**

*The figures reflect the status of registered suspected contaminated sites in the Federal States. The individual figures are not comparable to each other since the Federal States do not use compatible definitions for the terms of suspected contaminated sites and abandoned industrial sites (for example, in Hesse only sites with proved contaminations are included).

7.1.2. *Methods and Processes for Remediation*

7.1.2.1. *Overview*

The final objective of any remediation measure is the elimination of risks and dangers that may arise from soil pollution when using the site for specific purposes. Principally, this can be achieved by the treatment of soil or groundwater to remove the pollutants or to reduce their concentration (decontamination measure); or by containment or fixation of the pollutants to interrupt or reduce the spreading of pollutants towards the relevant targets (safeguarding measure). Both types of remediation methods are applied and they are specifically defined as remediation measures in the German Soil Protection Act.

Safeguarding technologies were originally designed, developed, and extensively used for the remediation of abandoned waste disposal sites. However, in the 1990s they became more and more important also for the remediation of abandoned industrial sites.

Safeguarding measures include:

Surface sealing,
Vertical sealing (slurry wall),
Immobilization measures,
Passive hydraulic and pneumatic measures

Decontamination measures for soil include:

Thermal soil treatment,
Physicochemical soil treatment,
Microbiological soil treatment,
Soil vapor extraction.

Furthermore several *groundwater remediation* measures are applied. They are generally based on well known technologies used in the treatment of municipal or industrial sewage. For groundwater these measures are mainly performed aboveground after pumping (pump and treat). A presently intensive discussed, developed, and increasingly applied technology for the purification of groundwater is the placement of absorptive barriers into the groundwater stream, in order to remove the contaminants by absorption. These absorptive barrier wall systems are applied with and without additional hydraulic measures and work in two ways. On the one hand they act as a less permeable vertical barrier that prevents the contaminants from spreading into the broader groundwater regime, on the other hand they serve as a filter that slowly removes the contaminants from the groundwater by absorption. The advantage of the process is its cost effectiveness. The disadvantage is the very long period of time that is necessary for the purification of groundwater below the required concentration.

Soil decontamination can be principally applied in three ways:

1. Treatment at the natural location of the contamination without excavation of soil (in situ)

2. Treatment after soil excavation or groundwater pumping at the site (on-site)
3. Treatment after excavation and transportation to another site (off-site)

In situ soil treatment has the advantage that the soil compartment remains in its natural location and an excavation and subsequent backfilling is not necessary. Under this aspect, in situ measures are regarded as rather inexpensive compared to on-site/off-site technologies. In the practical application, however, the natural conditions at a specific site must be taken into account. The lower cost factor is certainly true for cases with homogeneous soil conditions and a limited pollutant spectrum. In the majority of cases with inhomogeneous subground conditions and a wide spectrum of pollutants, the effectiveness of in situ processes is restricted. In practice therefore, in situ applications are limited primarily to soil vapor extraction and with restrictions also to microbiological in situ treatments.

Further promising options for in situ soil treatment are in the research and development. These approaches for in situ thermal treatment aim at the vaporization of volatile organic compounds by in situ heating by high-frequency energy or hot air injection. The soil vapor is then collected at the surface and led to a surface treatment facility. Such techniques have been applied in pilot scale with quite promising results. However, they are rather in an outsider position compared to available and best demonstrated techniques and do not play a significant role on the remediation market. The same is true for an in situ soil washing concept that has been successfully applied on a large scale in Germany. The technology involved the high pressure injection of water into the soil, effecting the separation of pollutants from the soil particles in situ. On-site and off-site treatment is the standard procedure of soil decontamination now in Germany, whereas off-site treatment in stationary facilities is the main method.

Since the beginning of the 1990s the number of stationary soil treatment plants has tremendously increased (Fig. 22). In 1990, 22 soil treatment plants were either in operation or in planning. In September 1993 the number of operating treatment plants increased to 47 facilities with a total treatment capacity of 1.25×10^6 t/a (1 thermal treatment plant, 12 soil washing plants, and 34 biological treatment plants). In 1995 the number of operated soil treatment plants was 95 (3 thermal treatment plants, 23 soil washing plants, and 69 biological treatment plants). The total available treatment capacity was about 2.5×10^6 t/a. This figure already exceeded the request by the customers. According to information of the operating companies, the average degree of usage was only about 50 %.

Figure 22. Development of soil treatment plants in Germany

The latest figure on soil treatment facilities and capacities dated October 1997 [398]. At that time, 104 soil treatment facilities were offering their services all over Germany:

4 thermal treatment plants providing a total capacity of 168 000 t/a,
24 soil washing plants providing a total capacity of 1.5×10^6 t/a, and
81 biological treatment plants providing a total capacity of 2×10^6 t/a.

These plants provide an available soil treatment capacity of ca. 3.8×10^6 t/a in 1997. The average degree of usage was about 64% (Table 34).

Table 34. Soil treatment technologies and capacities in Germany in 1996

Technology	Capacity, t	Soil treated, t (average degree of usage)
Biological treatment	1 897 850	1 243 678 (65.5 %)
Soil washing	1 382 900	854 333 (61.8 %)
Thermal treatment	168 000	109 200 (65.0 %)
Total	3 448 750	2 207 211 (64.0 %)

In the next sections, the main processes for soil decontamination are briefly described followed by selected examples of decontamination plants that are working or have been working in Germany. Since safeguarding measures are becoming increasingly relevant for the remediation of contaminated soil, their main effects will be briefly described.

7.1.2.2. *Soil Treatment Processes*

7.1.2.2.1. Thermal Soil Treatment [400]

Thermal soil treatment processes are based on the principle of scrubbing pollutants from the soil into gaseous phase by supply of thermal energy; the elimination of pollutants occurs either by a pyrolytic process, by incineration, or by evaporation of pollutants, while avoiding a melting of the mineral soil matrix.

In general, two types of processes can be distinguished:

Thermal treatment by direct combustion of the material (incineration),
Thermal treatment by indirect combustion of the material (pyrolysis).

Both processes have in common the treatment of soil in a furnace (e.g., rotary kiln, fluidized bed, flystream reactor or sintering belt) to which, depending on the procedure, a receiving dryer can be connected as well as flue gas treatment, consisting of high-temperature postincineration and flue gas purification.

In the case of high-temperature postincineration, the waste gas is heated to 900 – 1300 °C so that the existing organic pollutants are completely oxidized. The flue gases from high-temperature postincineration are generally subjected to a multi-step purification in order to comply with the emission limit values required.

Thermal treatment is an available and best demonstrated technology. In practice, thermal soil treatment is mainly performed using medium temperatures of 600 – 700 °C. High-temperature treatment is exclusively applied to highly contaminated soil.

Thermal soil treatment processes are suitable for almost all soil types and pollutant groups (see Table 35 and 36). As a rule, they are only limitedly applicable for the treatment of heavy-metal contamination. At high treatment temperatures, however, heavy-metal compounds become largely immobilized in the soil matrix. High degrees of cleaning, usually > 90 % are achievable for aliphatic hydrocarbons/petroleum products, polycyclic aromatic hydrocarbons (PAHs), volatile chlorinated hydrocarbons, aromatic hydrocarbons, polychlorinated biphenyls (PCBs), halogenated hydrocarbons, cyanides, organic nitro compounds, pesticides, as well as dibenzodioxins and dibenzofurans, depending on treatment temperatures (ca. 350 – 1200 °C) and residence times in the decontamination process (15 – 60 min).

Organic compounds containing N, S, O, P[b]		X	
Hg, Cd, As, Se, Zn		X	
Other heavy metals[c]			X

[a] BTEX: Benzene, toluene, ethylbenzene, xylene; these compounds include all organic chlorinated compounds such as PCB, PCP, CF, chlorinated pesticides and PCDD/PCDF. Other halogenated compounds can, in general, be treated. At present, they are not significant in practical terms.
[b] NSOP compounds include all organic compounds that are not halogenated and contain at least one of the four elements N, S, O, P. They include, e.g., pesticides, TNT, etc.
[c] Non-volatile heavy metals.

Direct Heating Process of Umweltschutz Deutzen GmbH. The first thermal soil treatment plant in the new Federal States was erected and operated by Broerius Bodensanierung und Umwelttechnik (Borna) on a former coal briquette factory site in Deutzen in December 1994. The plant is now owned by the Umweltschutz Nord Group and operated by the company Umweltschutz Deutzen. The treatment plant has been licensed under the Federal Mining Act and the Federal Technical Instructions on Air Quality Control. The direct heated rotary kiln is operated at average treatment temperatures between 520 and 600 °C. The treatment capacity is about 80 000 t/a (150 000 t/ a are planned). The plant includes a roofed storage for contaminated soil with a capacity of 300 000 t. The same direct heating process has been operated since 1989 by the Broerius company in The Netherlands.

Terravec Process of Harbauer Umwelttechnik. The Terravec process of Harbauer Umwelttechnik, Berlin is an example for an innovative technology that was used very successfully in on-site operation. The plant described below has now disappeared from the market since it gained not enough interest for further applications because of the high costs of the process and sufficient treatment alternatives in existing stationary plants.

The Terravac process was used for the treatment of highly contaminated fine grain fractions, especially from wet mechanical soil cleaning (soil washing). This vacuum distillation plant worked in the low temperature range and was brought into operation in June 1993 in Marktredwitz (Germany). This plant was especially designed for the treatment of soil contaminated with mercury and mercury products. Figure 23 shows the plant under construction. The plant combines a wet mechanical soil separation, concentrating pollutants in the fine grain fraction, with a subsequently thermal distillation treatment. The fine grain suspension coming from the soil washing is dewatered and dried and then fed via vacuum locks to the vacuum distillation plant. In the vacuum distillation reactor the soil is heated to temperatures between 350 and 450 ° C at 5 to 15 kPa. Mercury evaporates under these conditions and can be recovered by recondensation. After passing the vacuum distillation unit the soil is cooled and mixed with washed coarse grained material from the soil washing process. The plant was in operation from 1993 to 1996, treating about 50 000 t of mercury-contaminated soil.

Figure 23. Vacuum distillation plant (Terravac Process) of Harbauer Umwelttechnik Berlin under construction at Marktredwitz

7.1.2.2.2. Physicochemical Soil Treatment/Soil Washing [401]

Physicochemical processes are mainly washing processes. The applied soil washing processes mainly use water as extractant, adding solubilizers, e.g., surfactants, if necessary. Moreover, there are processes that use inorganic and organic solvents.

Common to all soil washing processes is that the pollutants are stripped from the grain by means of mechanical energy and transferred to the liquid and gaseous stage or eliminated with the finest soil fraction. In doing so, water is used as dispersion, solvent, and transport agent; the efficiency can be increased by additives, depending on the type of pollutant. The pollutant quantity remains constant in all the processes outlined. After the process the pollutants are present in a concentrated form.

In general, the following steps are required in the soil washing facilities:

Preparation of the feedstock,
Wet decomposition,
Separation of light/high-density solids (sorting),
Finest grain separation,
Separation of process water and rinsing of washed soil,
Process water circulation,
Wastewater purification,
Waste air purification

The basis for the separation of pollutants (soil washing) is wet cooking. The aim is to achieve a maximum dispersion of the solids and to promote the separation of pollutants by supply of kinetic energy.

In addition, chemical additives, which facilitate overcoming the adhesive forces between soil particles and pollutants, are frequently used.

The application of soil washing processes mainly depends on the content of extremely fine grains in the soil. Fine-grained soil types (e.g., loam, clay, loess) can be washed sufficiently with these processes only to a limited extent since the fractions with a small particle diameter contain the largest pollutant load as compared to their mass. Thus, the energy required for washing increases with decreasing grain diameter, i.e., depending on the process, the energy necessary for the separation of pollutants cannot be provided economically.

Likewise, the limits of washing processes depend on the type and distribution of pollutants in the soil. Tables 37 and 38 provide orientation for the assessment of possible applications for soil washing processes. Moreover, there are limits to this process if the pollutants are viscous (e.g., tar) since they could cause malfunctions by smearing plant components. It is also not reasonable to use wash processes for pollutants that are incorporated into porous components and/or in cases where the pollutant is glued together with the mineral grain due to the washing medium and cannot be separated.

Table 37. Suitability of soil washing processes depending on the type of soil

Heavy metals	X	

High-Pressure Washing Process of NORDAC. Since l986 the high-pressure washing process of Klöckner – Oecotec, Duisburg has been used by the soil washing company Afu, Berlin, at various Berlin sites. This process has been developed in The Netherlands. The centerpiece of the washing plant consists of a high-pressure steel jet tube, in which water under high pressure up to ca. 35 N/mm^2 impinges on the pollutant-laden soil and bring about a separation of pollutant and soil particles. This process is usable for a broad pollutant spectrum. A development of Klöckner – Oecotec based on this principle started up in April 1989 on the former site of the Mannesmann Röhrenwerke in Düsseldorf-Lierenfeld. The Oecotec high-pressure soil washing plant 2000, which consists of 50 standard containers and is equipped among other things with a three-stage high-pressure steel tube uses steam injections to partially dissolve the pollutants before the treatment in the high-pressure steel tube. This plant was subsequently transferred to contaminated sites in Hamburg, Stuttgart-Bad Cannstatt, Munich, and Thale. In 1992 the plant was sold to the GFA company in Thale. Figure 24 shows this plant at the site of use in Düsseldorf-Lierenfeld.

Since 1991 a further development of this process has been in continuous operation on the site of the North-German Contaminated Sites Remediation Center (Norddeutsches Altlasten-Sanierungszentrum, NORDAC) in Hamburg. The technical capacity of the plant is about 100 000 t/a. Since the beginning of operation about 500 000 t of contaminated material has been purified with the NORDAC soil washing plant.

Figure 24. Oecotec high-pressure soil washing plant at the first site of application in Düsseldorf-Lierenfeld

7.1.2.2.3. Microbiological Soil Treatment [402] (⟶ Bioremediation)

Microbiological decontamination processes make use of microorganisms' ability to use organic compounds, in particular of biogenic origin, as nutrients (substrate). Under favorable conditions, the microorganisms convert these organic compounds to carbon dioxide, water, and biomass (mineralization), using the substrates as energy source and to build up their cells.

The processes mainly used in practice include biopiles and in situ procedures.

Biopile procedures are divided into *static* and *dynamic* processes. As opposed to static processes, in *dynamic processes* the soil, aggregated in layers of 0.5 to 3 m, is taken up periodically with special turning arrangements, homogenized and aggregated again, if necessary by adding water and nutrients. Figure 25 shows the tiling of soil at the microbiological treatment plant Ramstein (Bicoterra process) of the Sotec company.

Figure 25. Tiling of soil at the microbiological treatment plant Ramstein of Sotec (Bicoterra process)

In the *static process*, the necessary environmental conditions are created using irrigation and venting systems.
